**The Dissertation Committee for Tiffany Faye Kautz Certifies that this is the
approved version of the following dissertation:**

**Characterization of a Low-Fidelity Live-Attenuated Vaccine for
Venezuelan Equine Encephalitis Virus**

Committee:

Naomi Forrester, Ph.D., Mentor

Scott Weaver, M.S., Ph.D., Co-mentor

David Beasley, Ph.D.

Yuriy Fofanov, Ph.D.

Greg Ebel, Ph.D.

Dean, Graduate School

**Characterization of a Low-fidelity Live-Attenuated Vaccine For
Venezuelan Equine Encephalitis Virus**

by

Tiffany Faye Kautz, B.A., B.S., M.S.

Dissertation

Presented to the Faculty of the Graduate School of

The University of Texas Medical Branch

in Partial Fulfillment

of the Requirements

for the Degree of

Doctor of Philosophy

The University of Texas Medical Branch

May, 2018

Acknowledgements

I would like to thank my mentor, Dr. Naomi Forrester, for allowing me the independence and resources to grow as a scientist, as well as periodic chocolate drop-offs. I would also like to thank my co-mentor, Dr. Scott Weaver, for his additional guidance and supervision along this difficult path as Dr. Forrester became a Ph.D. mentor and I, a Ph.D.

I would like to heartily thank the many individuals who assisted me with laboratory techniques and allowed me to pepper them with questions and anxieties, including Edward (Ian) Patterson, Kelsey (Lane) Warmbrod, Kamil Khanipov, Elizabeth Jaworski, Dedeke Brouwer-Rockx, Mathilde Guerbois, Jonathan Auguste, Dawn Auguste, Rose Langsjoen, and Maria (Lola) Alcorn, as well as their mentors who allowed me to bother them, Drs. Scott Weaver, Yuriy Fofanov, and Andrew Routh. Additionally, thank you to my committee members who supported my various fellowship applications in addition to their guidance during this project: Drs. Beasley, Fofanov, and Ebel.

Of course, daily coffee breaks were always a much-needed respite filled with discussions of science and its problems (cloning should not be an art!), encouragement, and caffeine. Many thanks to Ian Patterson for beginning this tradition, as well as Gracie Thaxton and Sherry Haller for their commitment to our shared habit.

Lastly, but most importantly, thank you to my one-in-a-trillion husband, Pablo Coss, for his constant support and patience, as well as his beautiful illustrations for the introduction.

Characterization of a Low-fidelity Live-Attenuated Vaccine For Venezuelan Equine
Encephalitis Virus

Publication No. _____

Tiffany Faye Kautz, Ph.D.

Supervisor: Naomi L. Forrester, Scott C. Weaver

During RNA virus replication, there is the potential to incorporate mutations that affect virulence or pathogenesis. For live-attenuated vaccines, this has implications for stability, as replication may result in mutations that either restore the wild-type phenotype via reversion or compensate for the attenuating mutations by increasing virulence (pseudoreversion). Recent studies have demonstrated that altering the mutation rate of an RNA virus is an effective attenuation tool. To validate the safety of low-fidelity mutations to increase vaccine attenuation, several mutations in the RNA-dependent RNA-polymerase (RdRp) were tested in the live-attenuated Venezuelan equine encephalitis virus (VEEV) vaccine strain, TC-83. Next generation sequencing after passage in the presence of mutagens revealed a mutant containing 3 mutations in the RdRp, TC-83 3x, to have decreased replication fidelity, while a second mutant, TC-83 4x displayed no change in fidelity, but shared many phenotypic characteristics with TC-83 3x. Both mutants exhibited increased, albeit inconsistent attenuation in an infant mouse model, as well as increased immunogenicity and complete protection against lethal challenge of an adult murine model compared to the parent TC-83. The TC-83 3x mutant was selected for further study due its decreased replication fidelity. While infection of live mosquitoes with TC-83 and TC-83 3x proved difficult, *in vitro* mosquito cell

infection suggested increased attenuation of the TC-83 3x mutant in this host. TC-83 3x genetic stability was high, with no reversion of the 3 RdRp mutations during passaging *in vitro* and *in vivo*. Passaging of the TC-83 3x mutant using a reporter construct showed this mutant to have increased levels of recombination, as well as lowered fidelity. During serial passaging in a highly permissive mouse model, TC-83 3x increased in virulence but remained less virulent than the parent TC-83. These results suggest that the incorporation of low-fidelity mutations into the RdRp of live-attenuated vaccines for RNA viruses can confer increased immunogenicity whilst showing some evidence of increased attenuation. However, while in theory such constructs may result in more effective vaccines, the instability of the vaccine phenotype decreases the likelihood of this being an effective vaccine attenuation strategy.

INTRODUCTION

Chapter 1. AN INTRODUCTION TO RNA VIRUS FIDELITY AND VENEZUELAN EQUINE ENCEPHALITIS VIRUS

RNA and other nucleic acids are unique in their ability to store and replicate the information necessary for life. Unlike DNA, any changes made to an RNA molecule are immediately realized as proteins, resulting in many deleterious mistakes, but also the potential for rapid evolution. This is the life of an RNA virus, where the risks of error-prone replication are balanced by the ability to immediately respond to change.

Although virus research is arguably biased towards viruses that infect mammals, and thus humans, it is estimated that there are greater than 320,000 viruses that infect mammals alone, the vast majority of which are unknown (1). This and recent metagenomic studies (2, 3) suggest that only the smallest tip of the RNA virosphere has been identified (4). With the exception of viroids (5), RNA viruses have the highest mutation rate of all known species, ranging from 10^{-4} - 10^{-6} per round of genome replication (6-8). This is several orders of magnitude higher than DNA viruses (7) and thousands to tens-of-thousands of times higher than the mutation rates exhibited by bacteria and eukaryotes (9, 10). The abundance of RNA viruses demonstrates that the benefits of a high mutation rate may outweigh the risks. Therefore, it is important to understand how this successful balance of a high mutational burden came to be, beginning with the evolution and optimization of the RNA virus mutation rate.

RNA VIRUS REPLICATION

RNA-Dependent RNA Polymerase

Excluding retroviruses, the RdRp protein is required for RNA virus genome replication. Although each RNA virus family contains a unique RdRp with specialized features, there are conserved motifs and domains between different RdRps, as well as other polymerases.

The RdRp gene consists of 7 conserved motifs (A-G), each with its own specific and conserved fold (11). As a protein, the RdRp can be visualized as a right hand (Figure 1.1) with the finger and thumb subdomains connecting to form a channel for RNA replication, also known as the closed hand conformation. Forming the conserved catalytic core are the thumb, finger (motifs F and G), and palm (motifs A-E) domains. The thumb domain is responsible for RNA binding, usually in the minor groove of the double-stranded RNA following template recognition (12), as well as stabilization of the incoming NTPs (13, 14). It is also an integral member of the highly positively charged NTP tunnel, which likely acts as a pump to bring nucleotides into the RdRp (15). The finger domain assists replication by binding the major grooves of the RNA template to hold it in place, while the palm domain ensures the addition of the correct nucleotide to the RNA chain (12).

When the correct NTP enters the RdRp, Watson-Crick base pairing occurs between the NTP and the RNA template (16). This causes a conformational change that properly aligns motifs A and C, which bind and position the incoming NTP using metal ions (known as the two-metal-ion mechanism), as well as positioning of the RNA template by motif B (12). Motif D acts as the final checkpoint to confirm correct NTP addition by binding the NTP β -phosphate. This causes closure of the active site so that

the phosphoryl transfer reaction can occur, allowing the NTP to be added to the nascent RNA chain (17, 18). Of course, RdRps are notoriously unfaithful, and make errors approximately once per round of genome replication (7). Several residues in the RdRp have been found to be important to increasing and decreasing replication fidelity, which are further discussed in the RNA virus fidelity subchapter.

Other enzymatic activities, such as 5'cap synthesis, are also performed by RdRps, but these functions are distinct to different virus families. Alphavirus replication and other RdRp functions are further discussed in “alphavirus replication.”

RNA Virus Quasispecies

Most virus RdRps generate an estimated 1 mutation for every 10,000 bases, which is the approximate genome size of many RNA viruses (7). Theoretically, a mutation is equally likely to occur at every possible base during a replication cycle, with some mutations occurring more than once. This cloud of virus sequence diversity is termed a quasispecies, defined as a collection of closely related virus variants. These variants all cooperate together to contribute to the overall population phenotype (19, 20). Although the mutation rate for RNA viruses is high, with most mutations acting as deleterious or neutral depending on the effects on RNA secondary structure or protein sequence, the large population sizes produced during the rapid population growth of RNA viruses results in an overall effective strategy for swift adaptation (21).

While it is valid to assume that every position in the genome will mutate during the infection of each cell to result in a somewhat balanced amount of virus diversity at each position, this is not what actually occurs. Instead, hot and cold spots of diversity are produced (22). Hot spots likely represent malleable regions where mutations are unlikely

to decrease fitness, while mutations in cold spots are apt to result in adverse or possibly lethal outcomes for the virus. It is not well understood how these regions are determined, but the distribution of these hot and cold spots likely has ramifications for viral fitness.

For viruses, fitness is generally defined as the ability of the virus to replicate and produce progeny, usually measured by virus growth in cell culture (23). Even when examined *in vivo*, these methods can oversimplify or misrepresent the real world effects of the analyzed mutations, so it is important to be mindful of over interpretation of results. For example, the ability of a virus to form plaques does not necessarily correlate well with pathogenesis *in vivo*. Additionally, attenuation *in vitro* does not always translate to attenuation *in vivo*. For example, a clone-derived ZIKV was attenuated in mosquito *Ae. albopictus* C6/36 cells, but not in *Ae. aegypti* mosquitoes. (24). However, careful use of multiple measures of fitness can help to better understand the role of novel mutations during scenarios such as outbreaks or host switching. Additionally, there is the potential to predict high fitness mutations before they become actualized in the real world. For example, studies using PV and CHIKV have separately demonstrated that fitness-increasing mutations can be identified in ancestral virus populations (25, 26). However, it is much easier to validate a mutation that is already known to increase virus fitness than it is to predict one that will occur in the future, especially when many fitness-increasing mutations are reliant upon epistatic interactions (27-29).

The mutational spectrum for an RNA virus can be visualized as a 3D field, with multiple peaks and valleys representative of virus fitness (Illustration 1). The virus consensus sequence forms the foundation of the fitness landscape, allowing the virus population to explore this landscape through genetic drift, with the prospect of finding

and climbing new fitness peaks (30). This landscape is prone to change, with the magnitude, location, and frequency of the peaks and valleys changing through both time and space (20, 22). Due to the high mutation rates produced during RNA virus replication, the best strategy for an RNA virus to succeed in this plane is to produce a foundation composed of low rolling hills, termed survival of the flattest (31, 32). Thus, mutations away from the consensus sequence should not have large, detrimental effects as the sequence space is explored, but there is still the potential to find fitness peaks that aid in survival during a changeable environment. However, survival is not guaranteed, and the mechanisms that allow for the ubiquity of RNA viruses can also be used against them.

It is hypothesized that RNA viruses live on the edge of an error threshold, such that any increased mutational burden will cause the extinction of the virus population (30). This error threshold is difficult to define, and likely dependent upon a fluid environment, making the exact definition even more difficult, if not impossible (22). Pushing virus populations over this error threshold has been examined empirically by exposing RNA viruses to various mutagens, most commonly with Ribavirin, a nucleoside analog that is able to pair with cytosine or uracil. As the concentration of a nucleoside analog is increased, so does the virus mutation frequency, until finally the population succumbs to the pressure and becomes extinct (33-36). Recently, CVB3 and FLU mutants were engineered to be 1 mutation away from a stop codon for each leucine or arginine codon. These mutants replicated identically compared to the unaltered viruses. However, when exposed to nucleoside analog treatment, these viruses were very sensitive, with sharp decreases in virus titer, demonstrating how close viruses are the

edge of a tolerable mutation burden (37). When the nucleoside analog concentration is high enough to cause virus extinction, this is termed error catastrophe, broadly defined as an overproduction of mutations resulting in an unstable virus population that is unable to rescue itself from extinction (22).

The multifactorial effects of nucleoside analog treatment complicate the accurate detection of error catastrophe, however. For example, in addition to acting as a nucleoside analog, Ribavirin has been shown to have other functions (38), such as decreasing intracellular GTP levels, resulting in downstream effects such as interfering with the capping of RNA and impeding RNA virus transcription and translation (39-43). There is also evidence that Ribavirin treatment alters the immune responses (44) and inhibits viral RNA polymerases (40). Additionally, the nucleoside analog 5FU not only acts as an analog for uracil, but has also been shown to inhibit thymidylate synthase, required for the synthesis of DNA (45).

Work with fidelity mutants suggests that error catastrophe can still occur without pressure from a nucleoside analog. Regarding the study that mutated CVB3 to be more likely to produce stop codons, drops in titer were even more dramatic when a low-fidelity mutation was inserted into the genome, resulting in very little infectious virus (37). Additionally, other studies have found that low-fidelity mutants subjected to bottleneck passaging can quickly become extinct, providing further evidence of an error threshold (18, 46).

The ability of RNA viruses to rapidly restore their quasispecies diversity helps them survive severe bottlenecks, which occur many times within as well as between hosts (32). Bottlenecks occur when a population undergoes a reduction in the size of the

population, potentially changing the proportion of different genotypes. Importantly, bottlenecks act stochastically, which can have large effects on evolution as minority variants may come to dominate the population after a bottleneck, changing the course of evolution. It is not uncommon for viruses to undergo severe bottlenecks, with only a few virions seeding an infection or crossing barriers within the host (32, 47, 48). This could partially explain why so many viruses cause asymptomatic infections.

When viruses are passaged using bottlenecks, such as plaque-to-plaque transfers, this usually results in rapid attenuation of the virus (48-52). This attenuation is believed to be due to Muller's ratchet, which is the inability of an organism that does not reproduce using sex (e.g. viruses) to revert mutations that reduce fitness, resulting in an over-accumulation of deleterious mutations and possible, although unlikely, virus extinction (51). Interestingly, viruses attenuated by bottleneck transfers can be rescued by just a few large population passages (36), and there is evidence that quasispecies can retain memory of previous infections (i.e. minority variants previously associated with fitness gains in a different environment tend to remain in the virus population unless removed by bottlenecks), possibly aiding in this rescue (53, 54).

Another compelling piece of evidence for the existence of an RNA virus error threshold is the conserved host APOBEC protein family (55). Members of this family are cytosine deaminases, which change cytosine bases to uracil. Some of these members, such as AG3, appear to have antiviral functions, acting primarily by targeting and mutating retroviruses, such as HIV (56). This demonstrates that mutating a virus' sequence is an effective mechanism of protecting the host.

Advances in sequencing have allowed for a much better understanding of the subtle variation found within virus populations. Research using fidelity mutants as controls will be necessary to better understand quasispecies dynamics and how this correlates with important factors such as LAV safety, virulence, and host jumping.

RNA Virus Recombination

For RNA virus recombination to occur, at least two viruses must infect the same cell. Recombination can occur for any RNA virus, but positive-sense, monopartite RNA genomes that replicate using an RdRp will be the focus of this subsection.

RNA virus recombination primarily occurs when the RdRp switches from the RNA strand being replicated to a new RNA strand (i.e. copy choice recombination) or, less frequently, by ligating together cleaved RNA strands. Both homologous recombination, where the RdRp switches to a template with high sequence similarity, and nonhomologous recombination, where the RdRp switches to a template with low sequence similarity, can occur (Illustration 1.2). However, because homologous recombination is more likely to result in viable virus genomes, these are more likely to be identified (57).

It is not well understood why recombination occurs in all cases, but it is more likely to arise in regions with high amounts of RNA secondary structure and AU-rich sequences (57). Additionally, other factors, such as sequence homology between the two RNA strands and altered replication kinetics have been implicated in changing the rate of RNA recombination (57).

Depending on the RNA virus family, recombination is believed to be highly common (e.g. *Picornaviridae* (58)) or uncommon (e.g. *Flaviviridae* (59)). Even in virus

families not believed to undergo recombination frequently, DI particles (i.e. viruses with large deletions in their genomes that require a helper virus and interfere with the growth of untruncated virus) have been frequently observed (60). These DI particles are usually observed *in vitro* (60, 61), and are thought to be an artifact of passaging virus at high MOIs, but have also been found *in vivo* (62).

The importance of recombination to RNA virus evolution is hotly debated, and likely differs depending on the virus. Indeed, it may be an artifact of the RdRp, with the quasispecies produced during replication, as well as the large population sizes, as the true forces under selection for high RNA virus fitness (57). A PV mutant with a decreased ability to recombine was recently isolated (63). Interestingly, no change in fidelity was observed, suggesting that the two mechanisms for RNA virus genome evolution are not necessarily connected. This may not be true in all cases, however, as a low-fidelity SINV mutant was found to create more DI particles, indicating a link between fidelity and recombination for this virus (64).

The advent of new NGS techniques designed specifically to examine RNA virus recombination is now allowing recombination to be understood at the level of minority variants (65). This technology in combination with fidelity and recombination mutants presents an exciting new opportunity towards better understanding where recombination occurs in the virus genome, the frequency of this occurrence, and its role in RNA virus evolution.

RNA VIRUS FIDELITY

Poliovirus

The first and most famous RNA virus fidelity variant was first discovered by passaging PV in the presence of the nucleoside analog, Ribavirin (66). During this passaging, multiple synonymous transition mutations appeared in the RdRp, as well as one nonsynonymous mutation, G64S. When this mutation was inserted into the PV genome, this mutant was found to grow as well as the parent virus *in vitro*, was resistant to multiple nucleoside analogs, and was much slower to revert a mutated sequence necessary for PV guanidine hydrochloride resistance, all suggestive of a high-fidelity phenotype. Although the mutant grew well *in vitro*, G64S PV was slightly, but consistently outcompeted by the parent virus when passaged together (66). Later, it was reported that this mutant was attenuated *in vivo* using PVR transgenic mice, as G64S PV was able to grow well in the muscle when injected IM, but severely restricted in its ability to disseminate into the brain (67). This was not caused by an inability to grow in these tissues, however, as mice infected IC were completely susceptible to infection by G64S or parent virus.

Soon after these reports, Vignuzzi et al. (68) independently recovered the G64S mutant, also by passaging PV in cells cultured with Ribavirin. The G64S mutant acted very similarly in the hands of a different lab, with no alteration of growth kinetics *in vitro*, as well as reduced lethality *in vivo* and restricted tissue tropism, with G64S virus unable to infect the CNS when introduced by the IM route. Confirmation of high-fidelity genome replication was performed by RT-PCR of passage 3 virus stock followed by high throughput TOPO cloning and sequencing of a fragment of the virus genome. This found the G64S virus population to be approximately 5.6 times less error-prone than the parent virus. Most intriguingly, artificial expansion of the G64S virus quasispecies caused this

virus to increase in lethality while still maintaining the G64S mutation. However, when virus isolated from these mice was used to infect naive PVR mice, the G64S mutant was attenuated once again. This experiment provided very strong evidence for the quasispecies theory of RNA virus evolution by demonstrating that it was the diversity in the population that caused severe virulence *in vivo*, not any single mutation.

Later, Vignuzzi et al. (69) demonstrated that other amino acids in this position were also able to increase fidelity, such as G64A and G64T, albeit to a lesser extent than G64S. These initial studies with PV provided a strong prototype for future fidelity variants to be compared against.

Common Characteristics of Fidelity Mutants

In the years since the identification of high-fidelity PV, a large number of fidelity variants have been identified from a diverse number of RNA virus families, such as *Picornaviridae* (18, 46, 67, 68, 70-79), *Togaviridae* (80-82), *Flaviviridae* (83, 84), *Caliciviridae* (85), *Arteriviridae* (86), *Orthomyxoviridae* (87, 88), and *Coronaviridae* (89, 90). The first fidelity mutants were identified similarly to the high-fidelity PV mutant by passaging virus multiple times in the presence of a nucleoside analog, usually Ribavirin. Over the course of this passaging, the virus titer would rise as it adapted to the nucleoside analog, and the full genome or RdRp would be sequenced until promising SNPs appeared. Of course, this usually revealed that many mutations had occurred, and these would be inserted individually or as a collection into the original virus using reverse genetic techniques and tested for fidelity perturbations. This is a rather laborious process with no guarantee of success, so most fidelity mutants have been identified by rationally targeting conserved residues that were previously implicated as fidelity regulators. Using

these different techniques, over 50 fidelity mutants have been identified and characterized. Although the virus families are highly diverse, fidelity mutants share many common characteristics.

One necessary test for altered fidelity is to examine resistance to different nucleoside analogs. High-fidelity viruses are resistant to multiple nucleoside analogs, likely due to decreased nucleoside misincorporation, which correlates with higher fidelity overall. Low-fidelity mutants are less straightforward. Low-fidelity mutants generated by mutating residues important for high-fidelity are more sensitive to nucleoside analog treatment, regardless of the analog. However, low-fidelity mutants identified during nucleoside analog passaging are resistant to the nucleoside analog used for the identification, but are not necessarily resistant to other analogs (74, 83, 88). In concordance with this, low-fidelity mutants have been shown to exhibit higher fidelity for the specific mutations selected against by the nucleoside analog, but lower fidelity for other mutations, balancing out to lower fidelity overall.

Fidelity mutants generally do not exhibit attenuation during 1-step growth curves, which are typically performed using HeLa or BHK cells. The only exceptions to this are the arbovirus low-fidelity mutants (82, 83), which exhibit significant attenuation in mosquito cells but not vertebrate cells, and the high-fidelity PV mutant (67), which was attenuated in primary mouse embryonic fibroblast cells but not HeLa cells. Replication kinetics assays may not be sensitive to small differences between viruses (e.g. due to slight differences in timing the beginning of the virus infection, collection times, and pipetting errors, it is difficult to determine if 2-3-fold differences in titer are accurate between different viruses), so if the RdRp is able to be isolated, a biochemical assay can

be used to determine the exact rate of nucleotide addition (further detailed in “Molecular and structural determinants underlying fidelity”). In brief, high-fidelity mutants incorporate nucleotides at a slower rate, but more accurately (38, 71, 77, 83), while low-fidelity mutants incorporate nucleotides at a faster rate, but with more mistakes (18, 46, 77, 83). These differences are sometimes severe enough to change the specific infectivity of a virus (i.e. the ratio of virus RNA to PFU) (46, 70, 82, 83, 89, 90) or relative fitness (66, 68, 76, 78-80, 88, 90).

Many different methods have been used to calculate fidelity changes. One method isolates virus RNA from EP stock or low passage virus, ranging from 1 to 5 passages. Many groups have used these stocks to measure mutation frequency as in the early PV studies, using RT-PCR followed by TOPO cloning to screen for variants. NGS analysis has improved dramatically since these first studies, so newer publications also include data showing the amount of diversity generated across the entire virus genome. Due to differences in NGS pipelines and diversity calculations, as well as differences in the number of virus passages, it is difficult to compare mutation frequencies from different papers. For example, differences in methods are likely why the HEV71 fidelity mutants (72) produce such a large difference in diversity relative to the other fidelity mutants (Figure 1.2). While using virus stocks grown in cells make it difficult to tease apart mutations promoted by selection versus inherent differences in the production of mutations, most fidelity mutants appear to produce ± 1.5 -2-fold change in diversity compared to the parent virus (Figure 1.2). Although these differences in diversity appear small, these alterations have been shown in multiple viruses to translate to significant attenuation *in vivo* (18, 46, 67, 69, 71, 73, 76-80, 82, 86, 87).

Fidelity mutants are generally attenuated *in vivo*, with increased survival and tissue restriction. It is not well understood why certain organs fail to become infected with fidelity variants, especially when different routes of inoculation are used, but this is likely due to increased sensitivity to host bottlenecks. IFN may be a factor, but this was only observed for a high-fidelity low-recombination PV mutant (91). Arbovirus fidelity variants are usually more attenuated in the mosquito host, with lower virus titers or even almost complete restriction (80, 82, 83). This pressure can be intense enough to select for complete reversion of the fidelity altering mutation, as observed for the low-fidelity CHIKV and SINV mutants (82).

Molecular and Structural Determinants Underlying Fidelity

To date, fidelity mutants have mostly been identified in the viral RdRp. The only exceptions are the coronavirus ExoN mutants (89, 90) and a mutation in the alphavirus helicase gene, nsP2, found to increase CHIKV fidelity (81). Coronaviruses are members of the Nidovirus family, some of which have evolved uniquely large RNA genomes (i.e. >20kb). The ability of these large RNA viruses to persist is credited to the ExoN gene, which is a proofreading exoribonuclease (92). When this proofreading function is ablated, RdRp fidelity drops by approximately 20-fold (89, 93). Interestingly, when a MHV ExoN mutant was passaged hundreds of times, fidelity slowly increased, likely due to compensatory mutations that occurred in ExoN, as well as the RdRp, but reversion of the original ExoN mutations never occurred (90).

Of the fidelity mutants that induce changes in the RdRp, structural analyses show negligible effects on RdRp structure. Instead, changes in fidelity appear to be mediated by alterations in RdRp kinetics and molecular dynamics (94).

RdRp NTP addition can be broken down into 5 steps (Illustration 1.3) (94). First, an NTP binds the RdRp, which causes a conformational change (step 2) and activates the RdRp (step 3). The NTP is then added to the RNA chain, leading to another conformational change and translocation of the RNA (step 4). Finally, the pyrophosphate leaving group is released (step 5), allowing the cycle to begin again. Steps 2 and 4 are rate-limiting, so fidelity changes are believed to only alter these two steps.

Fidelity mutants are usually found in motifs A and D of the RdRp active site (18, 46, 70, 71, 77), although other regions of the RdRp have been implicated in modulating fidelity. Mutations in the active site appear to alter fidelity by mutating residues that change conformation depending on whether the incoming nucleotide is correct or not by acting on the rate of polymerase incorporation, not the rate of NTP selection (74, 95, 96).

Unlike the RdRp mutations found in the polymerase core, high and low-fidelity G64S and H273R PV mutants are found on the periphery of the RdRp protein in the fingers domain. The current mechanistic theory for high-fidelity PV is that the G64S substitution interacts with other conserved residues in the RdRp active site, specifically motif A, to hydrogen bond to and orient the incoming nucleotide. The G64S mutation causes a misalignment of this hydrogen bond, which causes the misalignment to be even more severe when an incorrect nucleotide binds, thus increasing RdRp fidelity (97). Alternatively, low-fidelity H273R PV decreases fidelity by favoring an open state of the RdRp, which decreases the duration of this fidelity checkpoint, thus increasing the likelihood of NTP misincorporation (98).

Fidelity Mutants as Live-Attenuated Vaccines

RNA virus fidelity mutants are promising vaccine candidates due to increased *in vivo* attenuation and therefore an increased safety profile. High-fidelity vaccines for RNA viruses are of particular interest, because reducing the naturally high replication error rate should also increase the genetic stability of the vaccine. However, few of the above described fidelity mutants have ever been tested as vaccines.

Early in the fidelity variant literature, high-fidelity G64S PV was tested for its genetic stability and efficacy as a vaccine (69, 99). To examine stability, the miRNA let-7 was inserted into the PV genome, and cells expressing the miRNA were infected with parent or high-fidelity PV. The parent PV quickly mutated this miRNA sequence and began a productive infection, while G64S variant necessitated an additional 48 hours before it was also able to overcome this selection pressure. Interestingly, all G64S isolates contained the same deletion to remove the let-7 miRNA, while the parent virus isolates reverted using different nucleotide mutations and deletions. This suggests that although high-fidelity viruses are able to revert that these reversions are predictable, and can thus be anticipated and prepared for. When tested as a vaccine, the G64S mutant was shed approximately 100-fold less in feces than the parent virus. Additionally, G64S vaccinated mice produced slightly, but not significantly higher neutralizing antibody titers, and were able to fully protect against challenge.

More recently, a low-fidelity PV mutant, H273R (79), was found to provide complete protection when used as a vaccine, but only after a high dose of 10^7 PFU, which resulted in the paralysis of approximately 10% of vaccinated mice. Neutralizing antibody titers were correlated with protection, but the fidelity mutant appeared to require a 100 to 1000-fold higher dose to produce a similar neutralizing antibody titer to the parent virus.

While it is unknown whether H273R is prone to reversion, this mutant was shown to be very sensitive to bottlenecks, undergoing population extinction at a 10-fold higher PFU than the parent virus. This suggests that additional attenuating mutations would be necessary to improve the safety of this vaccine, but only if these mutations would not further reduce immunogenicity, necessitating a higher vaccine dose.

The only non-PV fidelity mutant to have been studied as a vaccine was a mouse-adapted SARS CoV (99). When the ExoN gene from SARS-CoV was mutated to remove its proofreading activity, the mutation frequency increased 11.5-fold, but there was no change in replication kinetics compared to the parent virus (99). This decrease in fidelity was stable, with a much higher accumulation of mutations during ExoN mutant SCID mice infection compared to a similar infection with the parental virus. Even after 3 murine passages, the virus remained attenuated, while the parent virus became completely lethal after 1 passage. As a vaccine, the mutant was well tolerated, even in immunocompromised hosts. The ExoN mutant was protective against challenge, and stimulated a neutralizing antibody response. However, how this compares to the parent virus or any other vaccine is unknown.

While the vaccines described above were designed to exhibit altered fidelity, these might not be the only LAV candidates with altered fidelity. Although empirically derived decades ago (100), the live-attenuated YFV vaccine 17D has been implicated as a putative high-fidelity vaccine due to multiple studies that have shown decreased 17D genetic variation compared to the YFV Asibi strain used to generate 17D (101, 102). The major success of 17D could be partially attributed to this increased fidelity, with only a small number of potential vaccine-associated YF out of the hundreds of millions of total

vaccinees (103, 104). This suggests that an attenuated fidelity mutant could indeed serve as a safe, effective vaccine.

ALPHAVIRUS

In the ongoing arms race between humans and arboviruses, arboviruses (arthropod-borne viruses) and their vectors are winning. The global incidence of arboviral disease is steadily increasing, and there remains a dearth of vaccines and antivirals for the overwhelming majority of these pathogens (105). Interestingly, all arboviruses, with the exclusion of African swine fever virus (106), are RNA viruses, suggesting that the diversity generated during RNA replication aids greatly during a two-host transmission cycle. Most arboviruses are from the *Bunyaviridae*, *Flaviviridae*, or *Togaviridae* virus families, all of which include pathogens of high importance to human health.

Of the two genera *Togaviridae* family, the alphavirus group is composed of 10 virus complexes, containing over 30 species (Figure 1.3), most of which are mosquito-transmitted arboviruses maintained in enzootic cycles (107). Species belonging to these different complexes are found worldwide, with members both on land and in the ocean. Due to the wide geographic distribution of alphaviruses, it is hypothesized that the original alphavirus members originated in the Pacific Ocean, where viruses repeatedly emerged on land and adapted to new hosts (108).

Alphaviruses are roughly classified as belonging to Old World or New World virus groups. However, this classification is not a hard rule, as some Old World viruses are found in the Americas, such as MAYV and AURA, and vice versa (109). Human disease caused by New World alphaviruses can result in encephalitic manifestations, while Old World alphaviruses are primarily associated with arthralgias (109). Although

human disease due to alphavirus infection is prevalent, there are no vaccines or antivirals that have been approved for human use.

Alphavirus Structure

Alphaviruses form an approximately 70nm in diameter icosahedron structure (T=4) (110), constituted by a nucleocapsid coated with an envelope (111, 112). The nucleocapsid is comprised of 240 capsid proteins, which encapsulate the viral RNA (111). Surrounding the nucleocapsid, the lipid envelope contains 80 spikes composed primarily of E2 and E1, with small amounts of 6k (113, 114) and occasionally E3 (109, 111). Spikes are formed by three heterodimer E2/E1 glycoprotein complexes, which twist together at the spike base in a counter-clockwise orientation. At the spike peak, this relaxes and the complexes separate (109).

Alphavirus Genome

The alphavirus genome is a 5' capped and 3' polyadenylated single-stranded RNA genome of approximately 11.5kb. The first two-thirds of the genome encode the nonstructural genes, while the last third of the genome encodes the structural genes under the control of a subgenomic promoter (Illustration 1.4) (109).

Alphavirus Lifecycle

ALPHAVIRUS ATTACHMENT AND ENTRY

Virus attachment occurs when the E2 glycoprotein binds a host-cell receptor, commencing cell-mediated endocytosis (Illustration 1.5) (115). Alphavirus host cell receptors are not well understood, but studies with SINV have shown that DC-SIGN and L-SIGN (116), especially when using virus isolated from mosquito cells, and laminin (117) are important for efficient SINV entry into mammalian cells. Heparin sulfate has

also been reported as a potential alphavirus receptor, but it is not well understood if this is just a cell culture adaptation or important in a natural virus lifecycle (118-120), although a recent study found heparin sulfate binding to increase EEEV neurovirulence in natural isolates (121). Occasionally, viruses are transported into the cell using the caveolar/raft pathway or other GTPase-dependent pathways, but the most common transportation pathway uses clathrin-coated pits (117).

Once internalized, these clathrin-coated vesicles fuse with an endosome (122, 123), leading to a drop in pH, which irreversibly changes the virion spike structure. E1 homotrimers then penetrate and fuse with the endosomal membrane, allowing release of the virus genome into the cytoplasm (124-126). While Old World viruses, such as SINV and SFV, fuse with early endosomes, studies with VEEV suggest that this is not universal, as VEEV also uses late endosomes (127). Additionally, most alphaviruses require cholesterol for efficient fusion, with the exception of VEEV (127), likely due to a serine residue at position 226 in E1, which when inserted into SINV and SFV reduces cholesterol dependence (128). This residue was also implicated in increasing *Ae. albopictus* mosquito CHIKV infectivity during the explosive 2005-2006 La Reunion outbreak (27, 28, 129, 130), as well as later outbreaks in Asia (131).

ALPHAVIRUS REPLICATION

After genome escape into the cytosol, the nsPs are immediately translated by host ribosomes (Illustration 1.5) (109). The nonstructural proteins, nsP1, nsP2, nsP3, and nsP4, are necessary for alphavirus genome replication (132). Also needed are the 5' and 3' UTRs, which bind the replication complex (133, 134).

Each nsP has specialized functions to contribute to replication. nsP1 aids in 5' capping of the virus genome and subgenome (135), and acts as the anchor for the replication complex (136). The nsP2 C-terminus contains a protease, and a helicase in its N-terminus (137, 138). The N-terminus of nsP3 is believed to bind host ADP-ribose 1-

phosphate phosphatase (139), while the C-terminus contains a hypervariable region that has been shown to interact with stress granules of the G3B family for Old World alphaviruses (140, 141) or fragile X syndrome protein family members for New World alphaviruses (142). These stress granules are required for virus replication complex assembly and increase its avidity to RNA (141). Finally, nsP4 is the RdRp, which has a high turnover rate due to an N-terminal tyrosine that targets the protein for degradation via ubiquitin-dependent proteolysis (143). The C-terminus of nsP4 shares similarity with other RdRps (144, 145), while the function of the N-terminus is unknown but necessary for replication (146). However, one function of the N-terminus is to add adenosines to the terminal end of the 3'UTR (132, 134, 147). Importantly, various amino acid mutations in nsP4 have been shown to alter binding to different nucleotides, suggesting that different protein residues are involved in the addition of each nucleotide (148, 149).

Pull-down experiments have shown that each nsP binds the other three nsPs (150). It is believed that as the polyprotein is cleaved, different conformations form, changing the virus genome strands that are replicated (109). Unfortunately, the structures for most alphavirus nsPs are unsolved or only partially solved, making it incredibly difficult to completely understand the steps that occur during replication. However, biochemical and genetic studies have made some characterization possible.

Due to a leaky opal stop codon between nsP3 and nsP4, there is an approximately 1:10 ratio of nsP1-nsP2-nsP3-nsP4 polypeptide to nsP1-nsP2-nsP3 polypeptide (151). Upon translation, nsP4 is immediately cleaved from the polyprotein chain (152). During early genome replication, when nsP1, nsP2, and nsP3 are still bound together, only minus-sense strand synthesis occurs (153, 154). This synthesis occurs in membrane-associated spherules, which are invaginations located on plasma membranes or virus-induced cytopathic vesicles (155, 156). nsP2 then cleaves the bond between nsP1 and nsP2 *in cis* (152). This begins the synthesis of positive-sense RNA, but minus-sense replication is still ongoing. Importantly, no subgenomic RNA is being produced. Finally,

the nsP1-nsP2 cleavage reveals an activator sequence in the N-terminus of nsP2, resulting in the cleavage of nsP2-nsP3 *in trans* by nsP2, and the production of positive-sense genomic and subgenomic RNA (152). This entire process takes approximately 3-4 hours (109).

ALPHAVIRUS GLYCOPROTEIN PROCESSING AND VIRUS EXIT

As the subgenomic RNA is translated, the capsid protein is automatically cleaved via autoproteolysis (Illustration 1.5) (157). The free capsid proteins bind full-length virus RNA using conserved sequences in the 5' end of the genome to form nucleocapsids (158).

The remainder of the structural polyprotein (PE2-6k-E1), travels to the ER, guided by a signal sequence in E3 (158). This complex anchors in the ER using hydrophobic sequences in E2 (159), and is cleaved between PE2 (the precursor to E2) and 6k by a signal peptidase (157, 160). In the ER, the glycoproteins are folded by host chaperones (161, 162) and become heavily glycosylated in the ER lumen, which are modified as the glycoproteins mature (163, 164). Following the ER, pE2 and E1 form heterotrimers (165), and travel to the Golgi complex, where E3 cleavage occurs by the host protease, furin (166-168). The E2-E1 heterotrimer migrates to the cell surface, where it anchors in the cell membrane. Finally, nucleocapsids interact with the C-terminal E2 glycoprotein tails (169), forming enveloped virions, which bud from the cell surface.

VENEZUELAN EQUINE ENCEPHALITIS VIRUS

VEEV is a mosquito-transmitted New World alphavirus found primarily in Mexico, Central America, and northern countries in South America (i.e. Colombia, Venezuela, etc.). It was first identified in the late 1930's from the brains of encephalitic horses (170, 171), and immediately realized to be similar to eastern and western equine encephalitis viruses (171).

VEEV can cause a spectrum of disease in humans, ranging from asymptomatic to flu-like illness to encephalitis (172, 173). While equine mortality during epidemic cycles is high, ranging from 19-83%, VEEV causes death in less than 1% of humans. However, encephalitis occurs in 4-14% of cases, most commonly in children, resulting in neurologic sequelae that can necessitate life-long medical care (174). The only therapeutic care available for VEE is supportive, and vaccines are only approved for use in equids.

VEEV is primarily found in swamps and forests, perpetuated in an enzootic cycle between rodents and enzootic mosquito hosts, the exact species of which are dependent upon the habitat (Illustration 1.6) (173). Spillover events from these enzootic cycles are common (175, 176), as has occurred in 1971 (177), 1995 (178), and 2003 (179). Occasionally, this spillover begins an epidemic, which is amplified between viremic horses and epizootic species of mosquitoes, resulting in a handful to hundreds-of-thousands of infected humans per outbreak (173).

Humans are believed to be dead-end hosts for VEEV (172). While equines usually only fall ill from epizootic strains (176), humans are equally susceptible to enzootic and epizootic strains (180). Spillover from the enzootic cycle is suspected to cause tens-of-thousands of human infections annually, but misdiagnosis with other circulating arboviruses (e.g. Zika virus, dengue virus) likely obscures the true incidence (180).

Within the VEEV serocomplex, there are six main subtypes and several more varieties within each subtype (Table 1.1). These subtypes were designated decades ago using cross-neutralization serology that does not always agree with more recent genetic analyses (181, 182). However, most spillover events from enzootic cycles have been from the ID and IE subtypes, as well as Mucambo virus (180). Occasionally, a mutation arises in the E2 glycoprotein that increases the outer charge of the virion. Such mutations can increase virulence and viremia in horses (183-185), as well as enhance infectivity in

mosquito vectors (186, 187). Sequencing and phylogenetic approaches have shown that IAB and IC outbreak strains are closely related to and interspersed between ID strains (188), demonstrating that small mutations in E2 can change virus serology and act as the source of major epizootic outbreaks.

Although VEEV causes many human infections using its natural transmission cycle, it can also be easily aerosolized, and is highly infectious via this route (189). This ease of aerosolization led to VEEV being developed as a biological weapon by the Soviet Union and United States during the Cold War (189). Due to this history, VEEV is categorized by the CDC and NIH as a class B agent, with epizootic VEEV strains further classified as select agents. Therefore, many vaccine candidates have been developed to protect against aerosol exposure.

VEEV Microevolution

VEEV, like other arboviruses, evolves more slowly over time than predicted by the error-prone nature of its RdRp (8). One hypothesis to explain this phenomenon is termed the trade-off hypothesis, which predicts that a two-host transmission cycle constrains fitness for a single host to permit the highest average fitness for both hosts, resulting in lack of frequent consensus sequence change (190, 191).

Microevolution studies designed to examine the trade-off hypothesis *in vitro* have generally found that virus adaptation occurs when arboviruses are passaged in one cell type (i.e. vertebrate or mosquito cells), but usually at the expense of replication fitness in the other host (192-198). However, when arboviruses alternate between mosquito and vertebrate cells, fitness increases commonly occur, usually on par with the fitness increases observed during single-host passage. Thus, most *in vitro* passaging research suggests the trade-off hypothesis to be false.

An interesting study examined the trade-off hypothesis *in vivo* using VEEV strains from the IC and ID subtypes (199). These two virus strains were passaged 10

times in *Ae. aegypti* mosquitoes, mice/hamsters, or alternating between the two hosts. As observed during *in vitro* passaging, no fitness gains occurred for mosquito-adapted VEEV in mice or hamsters, while fitness increased for murine-adapted virus. However, there was also no change in fitness for two-host passaged virus. In mosquitoes, VEEV IC and ID infectivity increased for mosquito-adapted virus, decreased for mouse-adapted, and exhibited no change during alternating passage. Importantly, this study evidenced the trade-off hypothesis to only be true during *in vivo* passaging, as these results were not repeatable *in vitro*. Giving further support to the trade-off hypothesis, few SNPs occurred during any of the passaging conditions, a common arbovirus host-cycling observation (192, 194, 197, 200), implying that all fitness gains were mediated by changes in the virus quasispecies. However, while this study supports the trade-off hypothesis, similar *in vivo* passaging studies with WNV and SLEV do not (200-202), suggesting the trade-off hypothesis is not universally applicable.

More recently, studies using NGS have shown that fitness gains in arboviruses are commonly associated with increases in sequence diversity (198, 200, 201, 203), including a new VEEV study that demonstrated a link between increased virus diversity and dissemination in the mosquito (204). At odds with this, low-fidelity SINV is attenuated *in vivo*, suggesting that virus mutant swarm composition is important for fitness (82). However, increasing the diversity of high-fidelity PV by Ribavirin passaging also increases its virulence (68), and low-fidelity SINV has been shown to also produce high amounts of DI particles (64), which is highly likely to also play a role in its attenuation. Thus, the interplay between fidelity and recombination complicates the understanding of these evolutionary processes.

Alphavirus family members display moderate levels of recombination. The most famous example is WEEV, which is a derivative of the nsPs, UTRs, and capsid of an EEEV-like ancestor combined with the remainder of the structural proteins from a SINV-like ancestor (205), which likely occurred 1,300-1,900 years ago (206). Under laboratory

conditions, alphaviruses readily recombine when cells are electroporated or transfected using multiple RNAs, resulting in attenuated viruses characterized by deletions and insertions/duplications (64, 207-210). While these earlier experiments were not conducted with VEEV, vaccine studies of attenuated VEEV constructs used to display antigens from other viruses (i.e. Lassa fever glycoproteins), were shown to frequently recombine with helper constructs, producing VEEV titers as high as 2×10^5 PFU/mL (211, 212). Lastly, while not strictly recombination, DI particles (213-216) and other deletion mutants (217, 218) are frequently observed for alphaviruses, although the *in vivo* relevance of these is not well understood. However, a recent study found recombination to occur *in vivo* when Atlantic salmon were infected with an SPDV deletion mutant and helper plasmid, hinting at the ability of alphaviruses to recombine in a living system (219).

Mouse Models for VEEV

Rodents play a large role during enzootic VEEV transmission, so mice are an ideal model to use to investigate various aspects of VEEV infection. Although VEEV is not universally lethal for rodents (220, 221), the most commonly used mouse models are highly sensitive, with as little as 1 PFU resulting in lethal infection, making this model ideal for testing vaccine safety (189). The varieties that are most commonly used are the BALB/c, C3H/HeN, Swiss Webster, and CD-1 varieties, which have intact immune responses. Mice infected with VEEV quickly lose weight, exhibit tremors and paralysis, and appear hunched and lethargic. It is believed that the brain infection is the major cause of lethality in mice, but lymphoid tissue damage is also severe (189).

When infected SC or ID, VEEV first infects dermal dendritic cells (222), which travel to the closest draining lymph node in as little as 4 HPI (223). From there, VEEV replicates and disseminates into the bloodstream at approximately 12 HPI, where the virus travels throughout the entire body. Most organs become infected with VEEV, but

titers are especially high in lymphoid tissues, such as the spleen and thymus, causing diffuse necrosis (223, 224). The most commonly infected cells in these tissues are mononuclear phagocytes (225). At approximately 24 HPI, VEEV enters the brain through the olfactory bulb and/or the trigeminal nerves (224, 226). Neurons are the main target in the brain (225), with infection causing necrotizing panencephalitis and myelitis (227). The virus is cleared from the serum by 3-4 DPI, but the permanent damage caused by VEEV results in death at 6-9 DPI (189).

When mice are infected via the aerosol route, the first tissues to be infected are the olfactory bulb and trigeminal nerves (227, 228). From there the virus is able to travel to the brain and cause lethal disease as it does following infection via the SC or ID routes. Because this infection route avoids the bloodstream, vaccines that stimulate a primarily IgG antibody response are not completely protective against aerosol challenge (229). To remedy this, some vaccines have been developed with the goal of increasing the proportion of IgA antibodies (230), which are found in the mucosa where aerosol infection first begins.

NHP Models for VEEV

Although mouse models are excellent tools for initial vaccine development, they do not accurately recapitulate the subtler VEEV disease observed in humans. For this, NHPs, most commonly cynomolgus and rhesus macaques, are much better, albeit less characterized, models.

Unlike mouse models, most macaques are able to survive VEEV infection, with the exception of IC inoculation. The most thorough VEEV NHP study infected 67 rhesus macaques IP with the Trinidad Donkey strain (231). As in humans, early illness is characterized by viremia, followed by fever and leukopenia (189, 231, 232). The main targets for VEEV in NHPs are lymphoid tissues, with lymphocyte necrosis in the lymph nodes and spleen, and the brain, usually characterized by multifocal perivascular cuffs

but not neuronal damage (231). Occasionally, encephalitis occurs later in infection, usually beginning approximately 6 DPI, although the likelihood and timing of this depends on the animal species, age, virus, and route of infection (189, 231). In macaques infected IN or via aerosol, the rate of brain infection is much more rapid, with lesions beginning at 48 HPI, and an overall more severe infection (233, 234).

Vertebrate Immune Correlates of Protection for VEEV

The first line of defense encountered by an RNA virus is the IFN response, which is a non-pathogen specific response to infection. Spotts et al. found that resistance to interferon α and β *in vitro* was correlated with epizootic potential (235), although this is controversial (236), and confirmed this *in vivo* by infecting immunocompetent or IFN receptor KO mice with the TC-83 vaccine strain or its virulent parent, the VEEV IAB Trinidad Donkey strain. While the Trinidad Donkey strain caused much more severe illness in immunocompetent mice, there was no difference in illness severity in the IFN receptor KO mice. This study and others suggest that an ability to resist IFN is key for alphavirus infection (237-241).

The innate immune system is not the only barrier to virus infection. It is well established that antibodies are the most important correlate of protection against alphavirus infection (242, 243), including VEEV (244). In fact, humans that do not produce antibodies against equine encephalitis viruses are at higher risk of succumbing to infection (245). These antibodies are typically directed against the envelope glycoproteins. E1 derived antibodies are usually non-neutralizing, while antibodies against E2 are neutralizing, but less cross-reactive (246). Additionally, passive transfer of antibodies is an effective means of protecting against VEEV SC and ID infection (244), but not aerosol (247, 248), demonstrating the importance of the antibody response, as well as its limitations against rapid-onset infections.

Lastly, the T-cell response for VEEV infection is not well understood. However, Th₁ cells are found in high numbers post-vaccination with TC-83 (249), suggesting a predominately inflammatory response. Additionally, when $\alpha\beta$ -T cell receptor KO mice were infected IN with TC-83, they became chronically infected and exhibited high virus titers in the brain, suggesting that T-cells are critical for virus clearance during VEEV aerosol infection (250).

Mosquito Models for VEEV

VEEV infection of the mosquito typically begins with infection of the posterior midgut epithelial cells (251). Dissemination into the hemocoel follows this, as well as infection of peripheral tissues, such as the salivary glands. Once the salivary glands are infected, VEEV accumulates in the apical cavities, awaiting transmission to a vertebrate host (173). A disseminated infection typically occurs over the course of 2-14 days, depending on the vector and the virus strain. Although a large number of mosquitoes have been confirmed as VEEV vectors, including *Ps. confinnis* (252), *Ae. sollicitans* (252, 253), and *Ae. taeniorhynchus* (253, 254) as epizootic vectors, and a large number of *Cu. (Mel.)* species of mosquitoes as enzootic vectors (255-259), few of these have been studied rigorously in the lab.

The most commonly studied epidemic VEEV vector in the lab is *Ae. taeniorhynchus*. This mosquito is an aggressive feeder found on the eastern coasts of the Americas, particularly nearby salt marshes (260). It has been well established that epizootic mutations in the E2 glycoprotein greatly enhance VEEV infectivity for *Ae. taeniorhynchus* (185, 187). However, a tight bottleneck occurs during midgut infection, with only 28 cells infected on average with an epidemic strain of VEEV IC, 3908 (251). Another stringent bottleneck likely occurs during vertebrate infection as well, with approximately 10 PFU transmitted by mosquitoes during *in vivo* transmission (261).

Using a natural, endemic vector of VEEV greatly increases VEEV infectivity, as demonstrated by multiple experiments using *Cu. (Mel.) taeniopus*. Infection of *Cu. (Mel.) taeniopus* requires as few as 5 PFU of enzootic VEEV (262). Unlike *Ae. taeniorhynchus* infection by epizootic virus, most midgut cells from *Cu. (Mel.) taeniopus* are able to be infected with enzootic strains of VEEV, such as 68U201 (263). However, the midgut still acts as a strong bottleneck, as evidenced by a study using marked virus clones (264).

The Mosquito Immune Response to VEEV

The mosquito immune response is composed of a variety of innate immune pathways, some of these with the ability to retain memory of previous pathogens. Information about the antiviral response against VEEV in the mosquito is lacking, so the information in this subsection is derived from studies using other arboviruses.

Undoubtedly, RNAi is the most important antiviral response in the mosquito. There are three RNAi pathways, which are best defined by the type of small RNA produced: small interfering RNA (siRNA), micro RNA (miRNA), and PIWI-interacting RNA (piRNA). The siRNA and miRNA pathways are stimulated by dsRNA. Dicer-1 (miRNA) or Dicer-2 (siRNA) cleave dsRNA into 21-24bp fragments (265-267). A single strand of these small RNAs is loaded into the RNA-induced silencing complex (RISC) and is used to identify similar or identical RNA sequences. RISC cleaves matching RNA strands, which targets them for destruction (268, 269). Alternatively, the PIWI pathway generates 26-31bp piRNAs from single stranded RNA precursors. These are loaded into a homolog of RISC and, like the siRNA and miRNA pathways, used to identify matching RNAs for destruction (270, 271).

Each small RNA pathway has been implicated in antiviral defense, but the clearly predominant small RNA antiviral pathway during acute viral infection is the siRNA pathway (265, 272). However, as the infection becomes chronic, or in the absence of an siRNA response (272-274), the number of piRNAs increase, and these appear to act to

control chronic arbovirus infections, likely through a virus-derived, circular DNA intermediate (275).

While miRNAs do not target many areas of the virus genome, siRNA and piRNA targets are more diverse and tend to cover the entire genome, with variation in targeting intensity and strand polarity (276). Studies examining the role of RNAi in virus diversity have found increases in sequence diversity in areas most targeted by RNAi (277-281), however this has only been closely examined using WNV. A study using SFV suggests that these hotspots may be decoys for the siRNA response to target (282), indicating the ability of arboviruses to subvert the host's antiviral response. However, more work is needed to better understand this balance.

The RNAi pathways are not the only immune responses that can aid in antiviral control. For example, knockdown studies have suggested that the JAK/STAT (283) and Toll (284) pathways help to control DENV infection. Additionally, apoptosis has been correlated with decreasing WNV infection (285) and transmission (286), but inhibition of apoptosis was found to increase SINV infection (287). Further work is needed to address the knowledge gap of how the mosquito immune response interacts with New World alphavirus infection.

Vaccines for VEEV

Primarily due to biodefense concerns, multiple vaccine candidates have been developed to protect against VEEV. The first vaccines made were using formalin-inactivated VEEV (288, 289). However, these vaccine preps were not always completely inactivated, resulting in many cases of vaccine-derived VEE in humans and animals (290, 291). There were several attempts to produce a live-attenuated VEEV vaccine, but there was no success until 1961, when the precursor to TC-83 was developed. TC-83 and its formalin-inactivated version, C-84, are the only vaccines approved to protect against VEEV infection in equines, although TC-83 and C-84 are also approved for IND use in

humans. The limitations of TC-83 have spurred investigators to generate more modern vaccines, which are also discussed below.

TC-83

TC-83 is a LAV for VEEV that was developed by passaging the virulent Trinidad Donkey IAB strain in guinea pig heart tissue (292). After 80 passages, the virus still caused clinical reactions in 85% of vaccinated humans, so a substrain was derived by plaque purifying the 78th passage in chicken embryo fibroblasts. After additional passaging in guinea pig heart tissue, a plaque-derived and mouse avirulent isolate was selected and termed TC-82 (i.e. tissue culture passage 82) (293). TC-82 served as the stock to prepare TC-83.

TC-83 attenuation and efficacy has been studied in multiple animal models, and is a commonly used control to compare against new VEEV vaccine constructs. While TC-83 is safe for adult mice and hamsters with few exceptions (294), the vaccine is lethal for suckling mice (295). TC-83 is able to protect mice and hamsters against subcutaneous exposure to VEEV, but protection against aerosol challenge is not always complete (296), likely because TC-83 predominately produces IgG, not IgA antibodies (297). When mice are exposed to TC-83 via the aerosol route, lesions occur in the brain, resulting in death in C3H/HeN mice, but not BALB/c (228), demonstrating incomplete neurological attenuation of the vaccine. Additionally, like wt VEEV, TC-83 is a teratogen in mice, resulting in an increased number of still births, as well as decreased litter sizes and infant survival post-birth (298). Interestingly, hamsters vaccinated with TC-83 exhibit early protection against VEEV, as well as some degree of heterologous protection against WEEV and EEEV, likely due to exclusion of the virus from cells as this protection vanished upon secondary challenge (299). In the macaque model, TC-83 was able to fully protect against SC challenge, but only protected approximately 40% of the monkeys post-aerosol challenge as evidenced by fever and low titer viremia (300).

TC-83 is available under IND status for at-risk military and laboratory personnel in the United States. When humans are vaccinated with TC-83, approximately 40% develop adverse effects (e.g. fever, transient leukopenia, and flu-like illness) and 20% fail to seroconvert (293, 301). Additionally, the neutralizing antibody titers generated following vaccination do not equally protect against all subtypes, especially against enzootic strains, and these titers wane slightly over time (297, 302). In humans with absent or low neutralizing antibody titers, boosting with C-84 (i.e. formalin-inactivated TC-83) was effective at stimulating a more robust immune response in most individuals (303). While C-84 is an effective booster for TC-83, vaccination with C-84 alone requires boosters to maintain seroconversion.

Although TC-83 is not available to the general public, it is still used as a vaccine for horses in some VEEV endemic countries. In horses vaccinated with TC-83, febrile illness and leukopenia can occur, but the majority seroconvert (304, 305). Some horses develop a low titer viremia post-vaccination, which may be enough to transmit the vaccine, as TC-83 has been isolated from field-caught mosquitoes (306).

The ability of TC-83 to potentially enter into a transmission cycle is concerning due to the instability of its attenuation. Mouse virulent isolates of TC-83 have been collected from vaccinated horses (295), and as few as two IC passages in infant mice can cause reversion of the attenuation (292). This instability is likely due to the reliance of TC-83 on only two attenuating point mutations, one in the E2 glycoprotein (nt position 8922, amino acid position 120) and another at nt position 3 in the 5'UTR (307, 308).

The E2 glycoprotein mutation is considered to be the primary determinant of TC-83 attenuation (307), and is believed to act by increased binding to heparin sulfate, a ubiquitous protein and common cell culture adaptation, allowing for rapid clearance of the vaccine *in vivo* (118). The 5'UTR mutation alters the ratio of genomic to subgenomic RNA synthesis (309), which enhances virus replication *in vitro*. However, this

overproduction causes attenuation *in vivo* by overstimulating the innate immune response, resulting in increased IFN sensitivity (309, 310).

In summary, TC-83 is a rather poor vaccine as evidenced by high levels of adverse events post-vaccination, subpar immunogenicity and protection, and unstable attenuation.

MODERN LIVE-ATTENUATED VACCINES

LAVs are typically cost-effective and protective after one dose, as all the below vaccines are. As the alphavirus lifecycle is better understood, this has allowed for rationally designed LAVs to become possible, of which there are several.

V3526 is a mutant of the Trinidad Donkey strain that was designed to ablate the PE2 cleavage signal, resulting in an immature glycoprotein. To prevent reversion of the PE2 mutations, it also contains a mutation in the E1 glycoprotein (311). V3526 is a safe and effective vaccine for rodents and primates, and is less likely than TC-83 to revert or enter a transmission cycle (312). However, this vaccine was abandoned during a phase I trial due to adverse effects, such as fever and flu-like illness (313).

A few LAV candidates have attenuated VEEV by mutating the subgenomic promoter sequence and inserting the IRES translation signal from encephalomyelocarditis virus into the genome to alter translation and replication, as well as to block mosquito infection (314-316). When this IRES was placed antecedent to the entire structural protein cassette of TC-83, attenuation was high, but immunogenicity was poor (314). However, when only the capsid gene was under IRES control, TC-83 (315) and VEEV IE strain 68U201 (316) IRES vaccines were fully protective against challenge. Infant mice infected SC with 68U201 IRES all succumbed to infection, while 100% of TC-83 IRES infected mice survived, suggesting that TC-83 IRES would be the safer IRES vaccine. Macaques vaccinated with 68U201 IRES tolerated the vaccine well, generated high neutralizing antibody titers, and were completely protected from aerosol-challenge,

demonstrating this to be a promising vaccine that should be further researched in humans (317).

There have also been a few modern LAVs that have not been as well characterized. For example, a SINV chimera expressing the TC-83 structural genes generated slightly lower neutralizing antibody titers than TC-83, but was much less virulent and able to protect against challenge (318). More recently, TC-83 that was further attenuated using a mutated capsid and packaging signal that did not induce CPE but grew well *in vitro* and was highly attenuated *in vivo*. This vaccine was a potent IFN stimulator in BALB/c mice, and was able to generate high levels of neutralizing antibody titers resulting in full protection (319).

INACTIVATED AND SUBUNIT VACCINES

Inactivated or subunit vaccines are very safe vaccine platforms, but are usually poorly immunogenic and require boosters.

As previously discussed, early vaccines for VEEV that inactivated the virus using formalin (288, 289) were unable to guarantee that each vaccine stock contained no live virus, resulting in multiple vaccine-produced infections (290, 291). It is believed that inactivated vaccines may have been the source of multiple epizootics during this period, as evidenced by later sequencing (320). Using inactivated LAVs has proven to be much safer. The two best characterized LAVs for VEEV, TC-83 and V3526, have both been inactivated using multiple mechanisms (303, 313, 321, 322). In BALB/c mice, there was no difference in efficacy between inactivated TC-83 and V3526 vaccines, but inactivation greatly reduced immunogenicity, so multiple boosters would be required for full protection from SC exposure. Additionally, these vaccines protect poorly against aerosol exposure (313). Formalin inactivated TC-83 (i.e. C-84) is currently approved for equines in the United States.

Subunit vaccines are used to present pathogen-specific antigens, either as a virus-like particle or protein recombinant. Recombinant baculoviruses expressing most or all of the structural proteins from the Trinidad Donkey strain of VEEV were highly immunogenic in BALB/c mice and able to protect against challenge (323). Immunogenicity dropped sharply when individual glycoproteins were used, however, suggesting that subunit vaccines would require the entire VEEV glycoprotein if this construct was to be further developed.

VECTORED AND REPLICON BASED VACCINES

Unlike subunit vaccines, vectored and replicon based vaccines are able to replicate their RNA, thus providing a more robust immune response.

The first replicon vaccine candidate developed for VEEV used the type 5 adenovirus platform, which requires complementation from cells expressing E1a, an adenovirus structural protein. This vaccine incorporated the E3-E2-6k structural genes from the VEEV Trinidad Donkey IAB strain, and was poorly protective when administered IN, especially against the VEEV IC subtype (324). When this vaccine was optimized for mammalian codons, higher levels of antigen were expressed, resulting in higher IgG levels. Upon aerosol challenge, 90% of vaccinated BALB/c mice survived, a 70% improvement upon the previous replicon vaccine.

Formalin-inactivated vaccines for the encephalitic alphaviruses (i.e. VEEV, EEEV, and WEEV) are typically administered to horses as a trivalent vaccine. However, protection is not long lasting, requiring annual boosters. To remedy this, one research group constructed separate VEEV replicons to express the glycoprotein cassette from each encephalitic virus, which were also modified to delete the furin-cleavage site (232). In BALB/c mice, the VEEV replicon vaccine was able to protect the majority against SC or aerosol challenge, although efficacy was decreased when all three vaccines were given together. Macaques vaccinated using a prime-boost strategy with the VEEV replicon

alone produced neutralizing antibody titers for viruses from all VEEV subtypes, but when given with the other vaccines, the only strong and consistent response was against a IAB strain. This interference is not uncommon for alphavirus combination vaccines (299, 325, 326). Macaques vaccinated with the VEEV replicon alone were not challenged, but monkeys vaccinated with all three replicons tolerated challenge well, with slightly lower fevers and only 1 of the 6 monkeys testing positive for viremia compared to 4 of the 6 mock-vaccinated controls.

The most recent vaccine candidate for VEEV replaced the structural genes of EILV, a mosquito-restricted alphavirus, with the structural genes of TC-83 (327). The resultant chimera, EILV-VEEV, was highly attenuated, with all infant mice surviving IC injection. Crucially, there was no evidence of lesions in the brain. CD-1 mice vaccinated using this construct generated high levels of neutralizing antibody and were fully protected post-challenge. Interestingly, EILV-VEEV was able to protect 40% of mice one day post-vaccination, whereas all TC-83 vaccinated mice perished. This may be due to the much higher doses of EILV-VEEV, which were 1,000-fold higher than the TC-83 dose, possibly generating higher levels of interference. EILV-VEEV's protective efficacy was reduced to 90% when delivered as a trivalent vaccine with other EILV chimeras. The high immunogenicity and safety of this vaccine warrant further studies in NHPs.

DNA VACCINES

The earliest DNA vaccine for VEEV encoded its structural genes under the control of a CMV promoter. This vaccine was delivered to the host via a gene gun, which uses pressurized helium to propel DNA into the host at high velocity (328). Post-vaccination, BALB/c mice were entirely protected against SC challenge, while 80% were protected against aerosol challenge. In guinea pigs, the vaccine was fully protective against SC challenge, but this dropped to approximately 83% when the vaccine was given in a cocktail with other DNA vaccines, again likely due to interference. Some guinea pigs

became viremic post-challenge. Interestingly, neutralizing antibody titers were absent or very low in both animal models, suggesting that these are not necessarily required for survival. When macaques were vaccinated 4 times with this vaccine and then challenged via the aerosol route, fever was reduced and only 1 of the 3 vaccinated monkeys became viremic, whereas all mock-vaccinated animals were viremic (329).

To improve upon this vaccine, multiple alternatives were designed. The first generated an array of CMV promoted DNA vaccines that were constructed using the envelope genes of various VEEV subtypes, as well as WEEV and EEEV (330). The only version that was able to fully protect BALB/c mice against a VEEV IAB strain challenge contained the E1 glycoprotein gene from a IAB strain and portions of the E2 glycoproteins from a VEEV IE strain and WEEV. A more recent collection of DNA vaccines included multiple HLA T-cell epitopes from the structural proteins of Ebola virus, Sudan virus, and VEEV. HLA-DR3 vaccinated mice generated low neutralizing antibody titers, and were poorly protected against VEEV or Ebola virus challenge (331). Lastly, an alternative CMV promoted vaccine used codon optimized (i.e. virus with codons optimized for protein translation in mammals) VEEV structural genes and was delivered via IM electroporation. This stimulated an earlier, more robust immune response in BALB/c mice, rabbits, and macaques, and was fully protective post-aerosol challenge (332).

Due to these promising results, the codon-optimized vaccine was granted a phase I clinical trial (333). Subjects were vaccinated once via ID (0.08mg or 0.3mg doses) or IM (0.5mg or 2mg doses) electroporation, and the vaccine was well tolerated with no severe adverse events. Neutralizing antibody titers appeared 40-70 days post-vaccination and correlated with dose, with all IM vaccinated subjects seroconverting, 83% of high dose ID vaccinated subjects, and 63% of low dose ID vaccinated subjects. These promising results suggest that further investigation of this vaccine, especially via the IM route, is warranted.

Finally, a more recent DNA vaccine used the entire TC-83 genome under the control of a CMV promoter (334). Termed an iDNA vaccine, when electroporated *in vitro* or *in vivo*, all of the TC-83 proteins are expressed, therefore beginning a self-perpetuating TC-83 vaccine. Moderate levels of neutralizing titers were generated in BALB/c mice, and all were protected against challenge.

IMPETUS FOR THIS PROJECT

During the replication of all RNA viruses, there is a high probability of incorporating mutations that affect virulence or pathogenesis due to the lack of an exonuclease proof reading function in the RdRp. For LAVs that utilize the virus' own replication machinery, this ability to incorporate mutations has implications for stability, as replication may result in mutations that either restore the wild-type phenotype via reversion or compensate for the attenuating mutations (pseudoreversion) by increasing virulence. There has been recent interest in increasing the safety of live-attenuated RNA virus vaccines by altering polymerase fidelity. Increasing virus fidelity results in a more clonal virus population that is less able to adapt to immune pressures or environmental changes. Alternatively, lowering virus fidelity results in an increased number of unfit progeny due to the higher number of mutations. Either way, altering RNA virus fidelity lowers virus population fitness, while also maintaining or increasing immunogenicity when used as a vaccine (69, 79, 99). However, this work has all been performed using virulent viruses, which are likely not attenuated enough for vaccine use.

To address this gap, the goal of this proposal is to test RdRp mutants of the VEEV LAV strain, TC-83, for changes in fidelity, virulence, immunogenicity, and genetic stability relative to parent TC-83. As TC-83 is a rather poor LAV, we believe that TC-83 is an excellent model to determine if altering fidelity can increase vaccine efficacy and safety. We hypothesize that TC-83 fidelity altering mutations will result in a safer, more

immunogenic LAV that is less able to enter and propagate itself using the VEEV transmission cycle. This will be examined using three aims.

Aim 1: Identify VEEV TC-83 fidelity mutant.

This aim will test the hypothesis that RdRp mutations identified during 5FU passaging of TC-83 will be fidelity-altering mutations, which will increase vaccine safety and immunogenicity in a vertebrate host.

Aim 2: Determine if low-fidelity TC-83 is restricted in the mosquito vector.

This aim will test the hypothesis that low-fidelity TC-83 is less fit than the original TC-83 in the mosquito.

Aim 3: Determine the stability of low-fidelity TC-83 mutations.

This aim will test the hypothesis that low-fidelity TC-83 is less able than the parent TC-83 to revert or pseudorevert attenuating mutations

Figure 1.1: RdRp structure of the FMDV 3D polymerase protein

The FMDV RdRp structure (335) was downloaded from the RCSB PDB and visualized in PyMol v1.8.4.0 (336). Structure (A&B) and surface models (C&D) are depicted. The RdRp is color-coded with the fingers as orange, the palm as purple, and the thumb as green. Location of conserved RdRp motifs as visualized on a right hand diagram (E).

Illustration 1.1: RNA virus mutational spectrum.

As RNA viruses mutate, the sequence space is sampled to find areas of higher fitness. This space is hypothesized to be changeable, so it is best for mutation-prone RNA viruses to exist in flatter areas of this space where decreases in fitness are slight.

Illustration 1.2: Recombination

Homologous recombination occurs when the RdRp switches from one RNA template to another, homologous RNA template during replication. Non-homologous recombination occurs when the RdRp switches from one RNA template to a dissimilar RNA template during recombination. The “X” indicates where RdRp movement to a new RNA template occurred.

Figure 1.2: Fold-change in fidelity mutant mutation frequency relative to the parent virus.

Most estimates are from TOPO cloning experiments, but if this information was not available fold-change NGS data was used. Mutations found outside the RdRp gene are indicated. Coronavirus data was excluded due to exceptional differences during RNA replication compared to the other RNA viruses.

Illustration 1.3: RdRp kinetics steps for NTP addition to an RNA chain.

First, an NTP binds the RdRp, which causes a conformational change “*” (step 2) and activates the RdRp (step 3). The NTP is then added to the RNA chain, leading to another conformational change and translocation of the RNA (step 4). Finally, the PP_i leaving group is released (step 5), allowing the cycle to begin again.

Figure 1.3: Alphavirus phylogeny.

Bayesian alphavirus phylogenetic tree kindly provided by Naomi Forrester.

Illustration 1.4: Alphavirus genome.

Illustration 1.5: Alphavirus lifecycle.

Alphaviruses enter the host cell via receptor-mediated endocytosis. The pH drops in the endosome, causing virion fusion with the endosome cell membrane. This allows for release of the virus genome, which is translated by host ribosomes to generate the nonstructural polyprotein. Due to a leaky stop codon between nsP3 and nsP4, nsP4 is only present in a fraction of these polyproteins. As the nsPs are processed to form various combinations of the replication complex, the virus genome is replicated. From the -RNA genome, the subgenomic (SG) RNA is transcribed and used to produce the structural proteins. The capsid protein is immediately cleaved and complexes with viral genomic RNA to form nucleocapsids. The remainder of the polyprotein is processed in the ER and Golgi complex, where it finally travels to the plasma membrane. Nucleosomes bind the cytoplasmic tails of the glycoproteins to complete virion formation, which bud and release from the cell surface.

Illustration 1.6: VEEV transmission cycle.

VEEV is primarily transmitted in an enzootic cycle between *Cu. (Mel.) spp.* of mosquitoes and rodents. Occasionally, a mutation will arise in the E2 glycoprotein, causing high-titer viremia in equids. This begins an epizootic cycle, which occurs between equines and various epizootic mosquito species. Humans can be infected from both enzootic and epizootic cycles, but are believed to be dead-end hosts.

Virus	Subtype	Geographic Range	Vertebrate Hosts	Mosquito vector	Human Disease	Endemic/Epizootic
VEEV	IAB	Trinidad, Peru, Colombia, Guatemala, Mexico, Texas	Horses, humans	Ae. and Ps. spp.	Yes	Epizootic

IDENTIFICATION OF A LOW-FIDELITY TC-83 MUTANT

Chapter 2. Characterization of a Low-Fidelity Mutant of TC-83 and its Utility as a Live-Attenuated Vaccine¹

INTRODUCTION

Due to the error-prone nature of the RdRp, RNA virus replication is characterized by a high mutation rate that results in increased genetic diversity of progeny viruses (337). This diversity can be utilized by the virus to evade and escape the immune system, as well as to adapt to new hosts. Maintaining the appropriate amount of virus diversity, which is typically approximately 1 mutation per genome (7) is of utmost importance to RNA virus survival within the host and during transmission. This is especially true for arboviruses, which utilize two distinct hosts to complete their transmission cycle. If the mutation rate of an RNA virus is too high, more unfit progeny will be produced due to the increased number of mutations, most of which are deleterious by chance. This results in a substantial decrease in viable genomes, and possible extinction of the viral population due to error catastrophe (338). Conversely, if the mutation rate is too low, little variation is produced, and the virus population becomes clonal and less able to adapt to diverse environments. Both scenarios reduce the overall fitness of the virus and can lead to extinction (50). This predicted lack of fitness with high or low-fidelity replication has been demonstrated experimentally with a number of viruses, including PV (66, 68), CHIKV (80, 82), WNV (83), SLEV (84), HEV 71 (72, 73, 339), FMDV (74-76, 78),

¹ Content of this chapter has previously been published: Kautz TF, Guerois M, Khanipov K, Patterson EI, Langsjoen RM, Yun R, et al. Low-fidelity Venezuelan equine encephalitis virus polymerase mutants to improve live-attenuated vaccine safety and efficacy. *Virus Evolution*, 4(1), vey004. Reproduced with permission.

SARS CoV (89, 90, 99), FLU (87, 88), NoV (86), and CBV3 (46, 70, 71). These viruses were all subjected to treatment with nucleoside analogs such as Ribavirin or 5'Fluorouracil, which increase the mutation rate and can lead to virus extinction, or by the insertion of mutations found to change fidelity in other viruses. Virus populations circumvent extinction by developing resistance to the nucleoside analog, sometimes by developing mutations in the RdRp that either increase (high fidelity) or decrease (low-fidelity/hypermulator) RdRp fidelity (i.e. the RdRp error-rate). When compared to unpassaged, wt viruses, fidelity mutants have similar growth kinetics *in vitro*, but are attenuated *in vivo* due to the alteration of diversity produced during replication, which hampers the ability of the virus to overcome bottlenecks in the host (67, 68).

The alphavirus genus, family *Togaviridae*, contains a number of important arboviruses that are distributed worldwide. Alphaviruses are classified as either Old World or New World viruses depending on their distribution. VEEV is a New World encephalitic alphavirus that circulates continuously in an enzootic cycle in the forests and swamps of northern South America, Central America, and Mexico, typically between rodents and mosquitoes. Spillover from this cycle is believed to cause tens of thousands of dead-end human infections annually (180). Periodically, the virus emerges to cause epizootic cycles in equids, which can also spill over into humans, sometimes resulting in hundreds of thousands of infections (183, 185, 340-342). Prior to the 1960's, equine epizootics involving high fatality rates were frequently recorded in VEEV-endemic areas. Since horses remain important components of the local agricultural economies within these regions, VEEV has had a major impact on the economic output of at-risk areas (343). Recent outbreaks in both Venezuela and Mexico demonstrate the ability of VEEV to re-emerge periodically from its enzootic niche (176, 344, 345), and some earlier outbreaks spread as far north as Texas (340, 346). Independent of these natural cycles of infection, there is great concern for the use of VEEV as a biological weapon due to its

high infectivity via the aerosol route. To address this threat, multiple vaccines have been developed to protect against VEEV infection.

The first human vaccine described for VEE, TC-83, was produced following 83 serial passages of the Trinidad donkey VEEV strain (subtype IAB) in guinea pig heart cells (292). Sequencing of TC-83 revealed eleven nucleotide changes, but attenuation was attributed to only 2 of these mutations; one in the 5' UTR and one in the E2 glycoprotein gene (307, 308). The reliance of TC-83 on only two point mutations for its attenuation increases the potential for reversion during vaccination, as well as instability during manufacturing. This concern has been supported by passaging in infant mice, where TC-83 reverted in a little as three IC passages (293). The retention of mosquito infectivity adds another safety concern for transmission from vaccinees to humans or equids, and the isolation of TC-83 from wild-caught mosquitoes in 1971 during an equine vaccination campaign underscores this risk (306). Due to these concerns, as well its incomplete immunogenicity (293, 301, 347), TC-83 is only approved for equids, but it maintains investigational new drug status for at-risk military and laboratory personnel.

The presence of a high mutation rate is thought to be one reason for the persistence of RNA viruses in the environment. However, high mutation rates also have implications for LAV's such as TC-83, which typically generate long-lived immunity and are cost-effective. LAV replication has the potential to restore a virulent, wt phenotype via one or more reversions or pseudoreversions. Such events can lead to safety concerns and possible adverse events following immunization (348). However, further increasing the natural mutation rate is also hypothesized to decrease the ability of the virus to successfully revert or pseudorevert through Muller's ratchet (51, 349), by the accumulation of deleterious mutations in asexual populations (e.g. viruses) during replication in the absence of efficient recombination. Additionally, deleterious mutations can also impair the ability of fitter viruses to replicate and increase in the population (49, 50, 350). Thus, the RNA virus error rate is finely tuned to allow for optimal virus

population health while also allowing for the production of mutations, which are key for adaptation to new hosts and environments.

The present aim was designed to determine whether mutations in the TC-83 RdRp that alter virus fidelity, i.e. increasing the mutational spectrum, can attenuate the virus further, without sacrificing vaccine stability or immunogenicity. This aim will test the hypothesis that RdRp mutations identified during 5FU passaging of TC-83 will be fidelity-altering mutations, resulting in increased vaccine safety and immunogenicity in a vertebrate host. In this aim, a virus containing 3 RdRp mutations was found to slightly decrease virus fidelity, while a mutant containing 4 RdRp mutations acted much like the low-fidelity mutant, but did not have altered fidelity.

MATERIALS AND METHODS

Cell cultures and viruses

Vero (African green monkey kidney), HEK-293 (human embryonic kidney), and Baby Hamster Kidney (BHK) cells were obtained from the American Type Culture Collection (ATCC) (Bethesda, MD) and maintained in DMEM (Gibco) supplemented with 10% Fetal Bovine serum (FBS, Atlanta Biologicals), and 500µg/mL gentamycin (Corning) in a 37°C 5% CO₂ incubator. C7/10 cells were maintained in DMEM supplemented with 10% FBS, 1% Minimal Essential Medium Nonessential Amino Acids (Gibco), 1% Trypose Phosphate Broth (Sigma), and 500µg/mL gentamycin in a 30°C 5% CO₂ incubator. U4.4 cells were maintained in Mitsuhashi and Maramorosch media (Sigma) supplemented with 20% FBS, 2% Sodium Bicarbonate (7.5%) (Gibco), and 500µg/mL gentamycin in a 30°C 5% CO₂ incubator.

Virus stock generation

Viruses were rescued from a TC-83 infectious clone (307) by electroporation using BHK cells. First, 5µg of TC-83 or the other RdRp mutants was linearized using the

restriction enzyme MluI (NEB) in a 50 μ L volume. 5 μ L of each digestion was mixed with 1 μ L 6x gel loading dye (NEB) and run on a 1% agarose (GeneMate) TAE (Fisherbrand) gel at ca. 100V for ca. 1 hour to confirm digestion. The remainder of the linearized product was purified using phenol-chloroform extraction. To do this, 50 μ L of nuclease-free water (Ambion) was added to the linearized DNA, followed by the addition of 100 μ L of phenol-chloroform (Fisherbrand). This was vortexed and centrifuged at 16.1 \times g for 5 minutes and the aqueous phase was transferred to a new 1.5mL tube. To this, 2 μ L of 5M NaCl (Ambion) and 100 μ L of chloroform (Fisherbrand) was added. This was vortexed and centrifuged again at 16.1 \times g for 5 minutes. The aqueous phase was then transferred to a new 1.5mL tube, 250 μ L ethanol (Fisherbrand) was added, and this was stored overnight at -20°C. After the tube was centrifuged at 16.1 \times g for 10 minutes, the ethanol was decanted and resulting pellet was washed with 300 μ L of 70% ethanol. Once a final 5 minutes centrifugation was complete, the ethanol was decanted and the pellet was allowed to dry for approximately 5 minutes before being reconstituted in 50 μ L of nuclease-free water.

In vitro transcription of the linearized DNA was performed in a 26 μ L volume using 2.5 μ L DTT (Invitrogen), 5 μ L 10X transcription buffer (Ambion), 2.5 μ L 10mM cap (NEB), 2.5 μ L 10mM rNTP (Roche), 5 μ L linearized DNA, 7 μ L nuclease-free water, 0.5 μ L RNaseOUT (Invitrogen), and 1 μ L of T7 (Ambion) (TC-83) or SP6 polymerase (Ambion) (RdRp mutants). This was incubated for 1 hour at 37°C and stored at -20°C overnight.

BHK cells were grown overnight in a T-150 flask to approximately 95% confluency the next day using complete media (DMEM supplemented with 10% FBS, 1% Minimal Essential Medium Nonessential Amino Acids, 1mM Sodium Pyruvate (Corning), and gentamycin. After one wash with PBS (Gibco), 0.05% trypsin-EDTA (Corning) was used to detach the cells from the flask. Once detached, 4mL of complete media was added to the cells, and this was transferred to a 15mL conical tube and

pelleted for 5 minutes at 125 X g. The media was decanted and the cells were resuspended in 7mL of cold PBS. This wash was repeated twice. Finally, the cells were resuspended in 450µL of cold PBS and stored on ice until added to 5µL of RNA from the *in vitro* transcription. This was gently mixed before being transferred to an EP cuvette with a 2mm gap (Fisherbrand). The sample was electroporated using a BTX 830 machine (Cole-Parmer) under the following conditions: 510V, 100µs pulse, 5 pulses, 184ms interval. The cuvette was left for 10 minutes at room temperature before the cells were transferred to a T-75 flask with 10mL of complete media and stored in a 37°C 5% CO₂ incubator. Every 24 hours, for 3 days, the supernatant from the flask was added to 2mL of FBS. The flask was then returned to the incubator after rehydrating the cells with fresh complete media. The supernatant was then clarified by centrifugation at 783 X g for 5 minutes at 4°C before being transferred to new 1.5mL tubes and finally stored at -80°C. Titers of the electroporated stock virus were determined by plaque assay using Vero cells.

Plaque assay

One day prior to infection, 6-well or 12-well Vero plates were seeded using 250,000 or 500,000 cells per well respectively to ensure approximately 90% confluency the following day. Virus stocks were serially diluted 1:10 8 times using 225µL DMEM (supplemented with 2% FBS and gentamycin) and 25µL virus. This dilution series was either performed using 1.5mL tubes (using vortexing to mix) or 96 well plates (using pipetting to mix). Media was then decanted from a cell culture plate and 100µL (12-well plate) or 200µL (6-well plate) of each dilution was added to a well. This was performed in duplicate. The infected monolayers were stored in a 37°C 5% CO₂ incubator for 1 hour and were gently shaken every 15 minutes to ensure an even infection distribution. After this incubation, a 0.4% agarose overlay (1 part 2% agarose (Lonza) in filter-purified water to 4 parts DMEM supplemented with 2%FBS and gentamycin) was added to each well, and the plates were returned to the incubator. Following a 48-hour incubation, the

monolayers were fixed for 30 minutes using 10% formaldehyde (Fisherbrand) before the agarose plugs were removed and the monolayer was stained with 0.25% crystal violet solution (Fisherbrand). The plates were then washed with water and allowed to dry before plaques were counted.

PFU per mL was calculated using the following formula: $\text{PFU/mL} = (\text{dilution} \times \text{number of plaques}) / (\text{amount plated})$, with “dilution” equaling the dilution at which the plaques were counted and “amount plated” equaling the amount of virus added when infecting the cells (i.e. 100 μ L for 12-well plates and 200 μ L for 6-well plates).

Nucleoside analog susceptibility

One day prior to infection, 24-well Vero plates were seeded using 125,000 cells per well to ensure approximately 90% confluency the following day. Cells from one well were counted the following day using a hemocytometer for MOI calculations.

Rescued viruses were tested for susceptibility to 5FU (Sigma) or Ribavirin (Sigma) in triplicate. Media was removed from the 24-well Vero plates, and replaced with 5FU or Ribavirin supplemented media (DMEM supplemented with 2% FBS, gentamycin, and 0, 10, 25, 50, 100, 200, or 300 μ g/ml of 5FU or 0, 50, 100, 200, 300, or 400 μ M Ribavirin) for 2 hours. The cells were then infected with 0.01 MOI of TC-83 or an RdRp mutant in a volume of 100 μ L and stored in a 37°C 5% CO₂ incubator. One hour post-infection, the inoculum was removed and media containing the pretreatment amount of 5FU or Ribavirin was added to the infected cells. The plates were then returned to the 37°C 5% CO₂ incubator. Cell supernatant was harvested 24 hours post-infection, supplemented with FBS to a final concentration of 20%, spun down at 3000 rpm for 5 minutes to remove cellular debris, and transferred to a new tube. These samples were stored at -80°C. Virus was titrated in duplicate using standard plaque assays.

Growth Curves – Vertebrate cells

To ensure that the inserted RdRp mutations did not interfere with viral replication, standard replication curves were conducted. One day prior to infection, 24-well Vero or HEK-293 plates were seeded using 125,000 cells per well to ensure approximately 90% confluency the following day. Cells from one well were counted the following day using a hemocytometer for MOI calculations.

Cells were infected at an MOI of 10 or 0.01 in a volume of 100 μ L and incubated for one hour in a 37°C 5% CO₂ incubator. After this, the cells were washed twice with PBS and overlaid with 0.5 mL of DMEM supplemented with 2% FBS and gentamycin. Virus was harvested by removing the entirety of the medium from three wells per time point. Harvested virus was supplemented with FBS to a final concentration of 20%, and clarified by centrifugation at 0.8 X g for 5 min. The supernatant was then moved to a new tube and stored at -80°C. Viral titers were determined by plaque assays.

TC-83 and RdRp mutant *in vitro* passaging

One day prior to infection, 6-well plates were seeded with 500,000 Vero cells or 1,000,000 U4.4 cells. The day of the infection, one well of cells for each cell type was counted using a hemocytometer and used to determine the virus dilutions necessary for an MOI of 0.1. Once diluted, media was decanted from the 6-well cell plates and 200 μ L was used to infect each well. These infections were performed using two replicates per virus. Following the infection, the plate was transferred to a 37°C (Vero cells) or 30°C (U4.4 cells) 5% CO₂ incubator for 1 hour with occasional shaking. When the incubation was complete, the inoculum was removed and 2mL of DMEM supplemented with 2% FBS and gentamycin (vertebrate cells) or the standard mosquito cell media was added to each well. The plates were then returned to the appropriate 5% CO₂ incubator for 48 hours.

After the 48 hour incubation, the virus was transferred to a tube with FBS to a final concentration of 20% FBS. This was centrifuged for 5 minutes at 0.8 X g and

transferred to a new tube. These tubes were stored at -80°C. Plaque assays using Vero cells were used to determine virus titer. Three total passages were performed.

Virulence assays in infant CD-1 mice

To study virulence and attenuation, six-day-old CD-1 mice (Charles Rivers Laboratories, Wilmington, MA) were inoculated IC with 10^5 PFU of virus in a volume of 20 μ l, or SC with 10^5 PFU in a volume of 50 μ l. Animals were weighed daily for two weeks and monitored for survival and clinical signs.

Vaccine study

7-week-old CD-1 mice were vaccinated SC with the original TC-83 virus or one of the RdRp mutants with 10^5 PFU in a volume of 50 μ l, or with PBS for unvaccinated controls (n=8 per cohort). Six weeks post-vaccination, animals were challenged SC with 10^5 PFU of wt epidemic VEEV strain 3908 (179), with daily monitoring for signs of illness, survival and weight loss.

Blood samples were collected from alternating cages of vaccinated mice for 3 days post-vaccination and 4 days post-challenge for viremia detection using plaque assays, as well as 5 weeks post-vaccination for antibody measurement by PRNT. Blood was collected via the retro-orbital route with capillary tubes (Fisherbrand), which were drained into 1.5mL tubes containing 225 μ l DMEM supplemented with 10% FBS and gentamycin. This was stored at 4°C overnight before being centrifuged at 783 X g for 5 minutes. The serum was then transferred to a fresh 1.5mL tube and stored at -80°C.

Plaque reduction neutralization test (PRNT₈₀).

One day prior to infection, 12-well Vero plates were seeded using 250,000 cells per well to ensure approximately 90% confluency the following day.

The following day, serum samples were heat inactivated for 1 hour at 56°C. Serum samples were then diluted 1:10 in 150µl of media (DMEM supplemented with 2% FBS and gentamycin) followed by 5 additional 2-fold dilutions. 75µL of each serum dilution was then added to a 96-well plate in duplicate, and an equal amount of TC-83 diluted to 800 PFU/mL was added to this and mixed well by pipetting. A TC-83 only control (i.e. no serum) was also made to determine the un-neutralized number of plaques. The 96-well plates containing the virus/serum mixtures were then incubated for 1 hour in a 37°C 5% CO₂ incubator. After this, 12-well Vero plates were decanted, and 100µl of virus/serum mixture was added to each well. These plates were incubated at 37°C in a 5% CO₂ incubator for 1 hour. Following this, a 0.4% agarose overlay (see plaque assay protocol) was added to each well, and the plates were returned to the incubator for 48 hours. Plates were then fixed and stained as in the plaque assay protocol.

PRNT₈₀ cutoff values were determined by counting the number of plaques from the virus-only well and multiplying this number by 0.2. Plaques were counted for each well, and titers were determined by the cutoff value (e.g. if no neutralization PRNT₈₀ < 1:20, if fully neutralized PRNT₈₀ > 1:640).

Virus Next Generation Sequencing

VIRAL RNA EXTRACTION

Viral RNA was extracted using the Qiagen viral RNA mini kit as per the manufacturer's protocol.

LIBRARY PREPARATION

Illumina sequencing was performed by the UTMB next generation sequencing core. Viral RNA from cell culture extracts were fragmented by incubation at 94°C for 8 minutes in 19.5 µl of fragmentation buffer (Illumina, San Diego, CA). First and second strand synthesis, adapter ligation, and amplification of the library were performed using the Illumina TruSeq RNA Sample Preparation kit as per the manufacturer's protocol.

Products were fragmented using transposons, then adapter ligation and amplification of the library was performed using the Illumina TruSeq RNA Sample Preparation kit under conditions described by the manufacturer (Illumina, San Diego, CA). Samples were tracked using the “index tags” incorporated into the adapters as defined by the manufacturer.

Sequence assembly and analysis

Illumina sequencing analysis was performed by the Fofanov lab at UTMB.

QUALITY AND FILTRATION

The quality for each sample/dataset was assessed using FASTQC (351). The paired-end reads were merged for each sample and then filtered to exclude reads with unknown characters (anything other than A, T, C, G) and low quality (<15 quality score), so that only high quality reads were used during analysis. Additionally, the first 16 bases of each read were trimmed due to nucleotide bias.

REFERENCE SEQUENCE

The analysis was performed using VEEV strain TC-83, complete genome (GenBank accession #: L01443.1)(308).

VIRUS DIVERSITY ANALYSIS

To determine virus variants, each sample was run through a novel rare variant pipeline developed by the Fofanov lab. The pipeline first maps each read to the reference VEEV genome with perfect match, then unmapped reads are re-mapped with 1 mismatch and added to the final map. The 34 base long reads used in the analyses were validated as viral sequences and not host sequences by analysis of the longest subsequences shared explicitly (no mismatches allowed) and longest similar (1 mismatch allowed) between viral and host genomes. Positions in which the number of reads mapped with mismatches was higher than perfectly mapped reads or coverage was below 100 were excluded from diversity calculations. Positions with non-zero mutation frequency were considered to be

variant positions. Mutation frequency per sample was calculated by summing the per position diversities and normalizing by the number of positions for which diversity was calculated. Shannon Entropy was calculated using the equation $-\sum_{i=1}^S p \log(p)/N$, where p equals the probability of mutation and N equals the number of base calls that can happen at a position (i.e. A, G, C, T, insertion, or deletion).

TC-83 3x and 4x backbone cloning

To rule out any differences in fitness caused by TC-83 backbone differences, the 3 or 4 RdRp mutations were inserted into the parent TC-83 plasmid. TC-83, TC-83 3x, and TC-83 4x were digested with SalI (NEB) and PspOMI (NEB) as per the manufacturer's protocol. Digestion was validated by running the entire contents of the digestion on a 1% agarose TAE gel. Bands were cut out and purified using the QIAquick Gel Extraction kit (Qiagen) as per the manufacturer's protocol. The RdRp mutations were ligated into the TC-83 plasmid using the T4 DNA ligase kit (NEB) as per the manufacturer's protocol and using a 1:3 insert to vector ratio. 4µL of the ligation was transformed using TOP10 competent cells (Invitrogen) as per the manufacturer's protocol, and 50µL of the transformation was plated on an LB-agar plate (Fisherbrand) supplemented with 100 µg/mL ampicillin (Sigma) and allowed to grow overnight in a 37°C incubator.

Colonies were picked the next morning and 8 were used to spike 5mL of LB supplemented with 100µg/mL ampicillin for miniprep processing (Clontech, as per the manufacturer's protocol) and Sanger sequencing. The primers 7246V (5'CCGTAGGAACTTCCATCATAG) and 7800C (5'CGTGGTTCTTCTTCTTCTTCC) were used to determine RdRp mutation insertion. Of the colonies positive for the RdRp mutations, one was used to spike 250mL of LB supplemented with 100µg/mL ampicillin. This was allowed to grow overnight in a 37°C incubator at 250rpm. The next morning, the bacteria were pelleted by centrifugation for 15 minutes at 2003 X g, and the plasmid

was purified using the NucleoBond Xtra Maxi Plus kit (Clontech). The purified plasmid stock was stored at -80°C.

Statistics

GraphPad Prism was used to perform all statistical tests, which are described in the text.

RESULTS

RdRp mutant identification and cloning.

Previous work in the lab identified three RdRp mutations during nucleoside analog passaging. Briefly, to identify mutations in the RdRp gene associated with changes in fidelity, TC-83 rescued from an infectious clone was previously used to initiate serial Vero cell passages in duplicate in the presence of Ribavirin, 5'Flurouracil (5FU), or Azacytidine (Aza). Viruses were titrated using plaque assays following each passage, and diluted to an MOI of 1 plaque forming unit (PFU)/cell for each subsequent passage. Following passages 19 and 23, the RdRp gene (nsP4) was sequenced. Three mutations were identified in both 5FU passages, and all were located in the 5' end of the RdRp gene: a G5724C mutation resulting in the amino acid change G14R, an A5794G mutation resulting in the amino acid change E37G, and a G5970A mutation resulting in the amino acid change A96T (amino acid numbers refer to nsP4 residues).

The three mutations identified following the 5FU passages were cloned into the TC-83 backbone in conjunction with a high fidelity mutation that was previously identified in a related alphavirus, CHIKV (C483Y, which corresponds to position 488 in TC-83) (80). Six mutants were created (Figure 2.1A), four of which were individual mutants, and two with multiple mutations: a 3x mutant including G14R, E37G, and A96T and a 4x mutant including G14R, E37G, A96T, and C488Y. All clones were rescued by electroporation into BHK cells, and were titrated using standard plaque assays on Vero

cells (352). All rescued mutants were viable, producing between 7-9 log₁₀ PFU/ml following electroporation (data not shown). Due to variation in EP stock phenotypes, each figure contains information that directs to an appendix with information about the various TC-83, TC-83 3X, and TC-83 4X stocks.

Replication kinetics

As the mutants included amino acid changes in the RdRp of VEEV TC-83, the viruses were subjected to standard replication curves (Figure 2.1B-C) on Vero cells (Figure 2.1B, appendix 2 stocks 1-3). No mutants showed significant differences from TC-83 by repeated measures ANOVA. Since Vero cells are IFN-deficient, and a previous study found high fidelity PV to be attenuated in a primary cell line (67, 77), we used HEK-293 cells to examine the effects of IFN on the replication of fidelity-altered viruses. TC-83, the 3x mutant, and the 4x mutant were subjected to one-step replication curves (Figure 2.1C, appendix 2 stocks 1-3). As in Vero cells, no significant differences were observed between the viruses and their TC-83 parent.

Resistance to nucleoside analog treatment

To confirm the ability of the RdRp mutations to confer resistance to 5FU treatment (Figure 2.1D, appendix 2 stocks 8, 9, 13). Vero cells were treated with 0, 10, 25, 50, 100, 200, or 300µg/ml of 5FU and infected with parent TC-83 or an RdRp mutant using an MOI of 0.01. Repeated measures ANOVA found no significant differences between the RdRp mutants and parent TC-83 when Vero cells were treated with 0-25µg/ml 5FU. However, treatment with higher 5FU concentrations caused titers for all single RdRp mutants to drop compared to parent TC-83, demonstrating increased sensitivity to the treatment. Of note, E37G was significantly different from parent TC-83 for all of the high 5FU concentrations ($p < 0.01$ for the 50µg/ml treatment, $p < 0.0001$ for the 100-300µg/ml treatments). A96T was slightly more resistant, with titers significantly

reduced compared to parent TC-83 when cells were treated with 100-300 μ g/mL ($p < 0.0001$). G14R and C488Y were the most resistant to 5FU treatment of the single mutants. Titers were only significantly reduced compared to parent TC-83 for the 200-300 μ g/mL treatments ($p < 0.5$ for G14R 300 μ g/ml, $p < 0.0001$ for all others). Due to the increased sensitivity of these mutants to 5FU, it was unlikely that these single mutations caused the resistance observed during the initial fidelity mutant selection.

Unlike the single RdRp mutants, TC-83 3x and 4x generally had similar or slightly higher virus titers compared to parent TC-83, suggesting increased resistance to 5FU treatment. TC-83 4x titers were significantly higher during the 50 and 100 μ g/mL treatments ($p < 0.01$ and $p < 0.0001$ respectively), and TC-83 3x titers were also significantly higher during the 100 μ g/mL treatment ($p < 0.05$).

To determine if the RdRp mutants reacted similarly upon exposure to another nucleoside analog, TC-83 and the RdRp mutants were exposed to various concentrations of Ribavirin (Figure 2.1E, appendix 2 stocks 8, 9, 13). No significant difference was observed, except for the G14R mutant, which displayed increased sensitivity ($p < 0.01$ for 100 and 300 μ M, $p < 0.001$ for 400 μ M).

Virulence in infant mice

To assess virulence, individual TC-83 mutants were injected IC into 6-day-old CD-1 mice at a titer of ca. 5 log₁₀ PFU (backtiters ranged from 1.9x10⁴-2.4x10⁵ per dose). Mice were weighed daily and the time of death was recorded (Figure 2.2A, appendix 2 stocks 1-3). The TC-83 3x mutant was significantly more virulent than the parent virus, with all animals succumbing by day 2 compared to TC-83, where mice began succumbing at day 3 ($p \leq 0.05$, Kaplan-Meier test). The mean time to death for parent TC-83 and all mutants except TC-83 3x was 5.36-5.54 days after infection, whereas TC-83 3x showed a mean time to death of 3.91 days.

Fidelity mutants have an impaired ability to overcome host bottlenecks, which results in reduced mortality and titer in certain organs (67-69, 99). To test this, individual mutants were injected SC into 6-day-old CD-1 mice to measure their ability to cause mortality (backtiters ranged from 6.2×10^3 - 1.35×10^5 per dose). TC-83 3x and TC-83 4x exhibited significantly reduced mortality as reflected in survival (Kaplan-Meier test, $p \leq 0.05$) when injected SC, compared to the original TC-83, and compared with IC injection in 6-day old CD-1 mice (Figure 2.2B, appendix 2 stocks 1-3). The remaining mutants caused similar mortality to original TC-83, suggesting no change in their ability to traverse bottlenecks to cause fatal disease.

Illumina sequencing for virus population variants

EP STOCK

EP stock was sequenced using Illumina NGS to determine early differences in virus diversity. TC-83 3x and 4x were the only RdRp mutants chosen for this analysis, because they were most likely to have altered fidelity as measured by a preliminary Illumina sequencing analysis measuring the diversity of one replicate of each RdRp mutant (data not shown), as well as the phenotypic tests depicted in figures 2.1-2.2. Due to low EP stock titers (appendix 2 stock 13 was used due to the depletion of stock 12) TC-83 4x coverage was low, so it was not analyzed. Mann-Whitney U tests showed no significant differences in virus diversity for TC-83 3x when using either mutation frequency (Figure 2.3A) or Shannon Entropy (Figure 2.3B) as a measure of diversity (Appendix 2, stocks 8, 11, 12).

Interestingly, diversity hotspots (Figure 2.3 C-D) were very similar. When using a cutoff of 0.2, 18 of the 22 TC-83 variants that were above this threshold were identical to TC-83 3x, which shared 18 of its 20 most common variants with TC-83. However, while the magnitude of these hot spots was well conserved between replicates, there was some

variation between TC-83 and TC-83 3x. For example, the peaks for C10371U and C10743G were much more prominent for TC-83 than TC-83 3x.

PASSAGE 1 STOCK

To examine how different hosts in the arbovirus transmission cycle may alter virus diversity, TC-83, as well as the 3x and 4x mutants, were passaged once using primate (Vero or HEK-293) or mosquito (C7/10 or U4.4) cells (Figure 2.4, appendix 2, stocks 7, 9, 12). Illumina sequencing showed that the 3x mutant produced a significantly higher amount of genetic diversity than parental TC-83, independent of the cell type used (Figure 2.4A). This, along with the previously discussed results, indicated that the 3x mutant is a low-fidelity variant. Interestingly, the 4x mutant did not demonstrate a significant increase or decrease in diversity compared to TC-83. Cell type had no significant effect on virus diversity, at least not after one passage. When the number of nucleotide positions containing diversity was examined (Figure 2.4B), the 3x mutant trended towards producing an increased number of positions with diversity, while the 4x mutant, again, looked much like the parent TC-83.

When examining peaks of diversity across the virus genome, some hotspots were conserved between the parent virus and RdRp mutants (Figure 2.5). These included nsP2 C2627A (Asp-Glu) and A2634Del (Met-stop), E2 U9561G (minus strand, Val-Gly), 6k C9978A (Ala-Asp), and E1 C11009A (minus strand, Arg-Ser). The parent TC-83 and, to a reduced extent, TC-83 4x both produced diversity hotspots in E1, but generally in different positions. In TC-83 4x, these consisted of C10032U (Ala-Val), U10356C (Val-Leu), and C11009A (Ala, minus strand, synonymous), while TC-83 had E1 hotspots at C10141U (Val, synonymous), C10371U (Ala-Gly), C10743G (Ala-Gly), C11009A (Ala, minus sense, synonymous), and U11269C (Asn, synonymous). Additionally, while there was no significant difference in diversity when different cell types were used (Figure

2.4), TC-83 3x appeared to have an increased number of diversity hotspots in C7/10 cells than the other cell types.

Furthermore, because TC-83 3x and 4x only appear to be resistant to one of the two nucleoside analogs tested (Figures 2.1 D-E), it was important to determine if this resistance is due to an alteration in the types of mutations being made by these RdRp mutants (Figure 2.4C). Indeed, both TC-83 3x and 4x produced fewer U-C mutations. As 5FU is a uracil analog and Ribavirin is not, this may explain the difference in nucleoside analog susceptibility.

PASSAGE 3 STOCK

As passage 3 stock is commonly used to decide whether an RdRp mutant is or is not a fidelity mutant (46, 68, 69, 77, 79, 89), due to the belief that the mutation rate has stabilized by this passage number (353), passage 1 stock from Vero and U4.4 cells were passaged two more times to determine changes in virus diversity (Appendix 2, stocks 7, 9, 12). While mutation frequency was significantly higher for the 3x and 4x RdRp mutants in U4.4 cells, there was no difference in Vero cells (Figure 2.6A). Additionally, while TC-83 3x exhibited consistently higher diversity as exhibited by Shannon Entropy, there was no significant difference compared to TC-83 (Figure 2.6B), likely to due to lack of statistical power. The mutation frequency of certain mutations had also changed (Figure 2.6C-D). While U-C mutations were still suppressed in the RdRp mutants in Vero cells (Figure 2.6C), after 3 passages, there was no longer any difference in U4.4 cells (Figure 2.6D). Additionally, for both cell types, U-G mutations became more frequent with TC-83 3x than the other viruses.

By passage 3, the number of high frequency variants (0.02 or higher) for all viruses had decreased (Figure 2.7), and approximately 50% of the high frequency variants were unique to the virus and passage series (40 unique variants of the 77 total variants, data not shown). Interestingly, the other 50% of the high frequency variants

were all conserved between TC-83, TC-83 3x, and TC-83 4x, with only one exception, U3559G (Val-Gly), which was found in both TC-83 3x passage series.

Immunogenicity and protection against VEEV challenge

Immunogenicity of the mutants was tested in an adult murine model previously used to test the efficacy of TC-83 (315). Adult CD-1 mice, 7 weeks of age, were vaccinated with 5 log₁₀ PFU in a 50µl volume via the subcutaneous route (Appendix 2, stocks 1-3). Animals were bled on days 1-3 after vaccination and weighed daily for 1 week and then again on days 11 and 14 (Figure 2.8A). Animals exhibited no weight loss and viremia was sporadic with no significant differences among any of the viruses (repeated measures ANOVA, Table 2.1). Four weeks post-vaccination, the animals were bled to assay neutralizing antibody titers (Figure 2.8B). All vaccinated mice exhibited a strong immune response as determined by a plaque reduction neutralization test (PRNT₈₀). The 3x and 4x mutants produced significantly higher mean neutralizing antibody titers compared to TC-83 (one-way ANOVA, p=0.0049 and 0.0012, respectively). Following challenge at 6 weeks post-vaccination with VEEV subtype IC strain 3908, which was used previously for similar experiments (315, 316), animals were weighed daily and monitored for survival (Figure 2.8C-D). All vaccinated animals showed complete protection from weight loss and death, whereas the sham-vaccinated animals all succumbed by day 9 post-challenge.

Variation in attenuation of low-fidelity TC-83 3x EP stocks

It was recently discovered that the infectious clones for TC-83 3x and TC-83 4x were made using a combination of two different TC-83 infectious clones, resulting in 3-6 synonymous differences between these RdRp mutants and the control TC-83 used for comparison (Table 2.2). Therefore, it was important to determine that these extra mutations did not affect virus fitness. The 3 or 4 RdRp mutations were inserted into the

control TC-83 backbone, and differences in replication kinetics were measured using a 2-step Vero cell growth curve (Figure 2.9A, Appendix 2 stocks 14-16). Repeated measures ANOVA found TC-83 3x to replicate slightly higher than TC-83 at 6 HPI ($p < 0.0001$), but there was no difference in replication after this time point. However, TC-83 4x had slightly, but significantly reduced growth at all time points ($p < 0.0001$ for 6 and 12 HPI, $p < 0.01$ for 24 and 48 HPI).

To ensure that the changes in infant mouse virulence were repeatable when the 3x and 4x RdRp mutants were in the same backbone as the control TC-83 (Figure 2.2A-B), 6-day-old CD-1 mice were injected IC or SC with 10^5 PFU of TC-83 3x or 4x mutants in the original (Appendix 2 stocks 8-9, 13, designated “old”), or control (Appendix 2 stocks 14-16, designated “new”) TC-83 backbone, as well as the control TC-83 (Figure 2.9B-C).

IC survival curves (Figure 2.9B) were similar to those in Figure 2.2A, with most mice succumbing 5-7 days post-infection. Backtiters of the inocula ranged from 4.8 - 8.8×10^4 PFU per dose. As before (Figure 2.2A), neither the “old” or “new” RdRp mutants were significantly more or less virulent than TC-83 as measured by Kaplan-Meier test. This suggests that regardless of the TC-83 backbone that these RdRp mutations do not alter virulence when administered intracranially, and that the significant difference in lethality observed in Figure 2A for TC-83 3x is likely dependent on the mutant spectrum produced post-electroporation or due to host variation.

SC survival curves (Figure 2.9C) were significantly different compared to Figure 2.2B. Instead of half of the 3x and 4x mutants surviving SC inoculation, all individuals succumbed by 12 days post-infection, regardless of TC-83 backbone. Inoculum back titers ranged from 3.5×10^4 to 1.1×10^5 PFU per dose. Although all mice succumbed, there was slight variation between the cohorts. For example, while the “old” TC-83 3x cohort survived an almost identical length of time compared to the TC-83 control group, the “new” TC-83 3x cohort survived an average of 9.6 days (Kaplan-Meier, $p = 0.0361$). The 4x RdRp mutants were similar, with the “old” backbone acting slightly more attenuated

than TC-83 (Kaplan-Meier, $p=0.0054$) and the “new” backbone showing no significant difference. More important than the differences in the RdRp mutant backbones was the difference between the initial SC survival curve (Figure 2.2B) and this repeat. While the “old” TC-83 3x and 4x mutants contained the same sequence and starting titer, the viruses were from different EP stocks. This and the IC survival curve results suggest that differences in the post-EP minority populations can result in variation in fidelity mutant attenuation.

DISCUSSION

Infectious diseases transmitted by arthropod vectors are difficult to control, and protecting the population via vaccination tends to be more effective than trying to control or eradicate the vector population. While LAVs tend to be cost-effective and immunogenic, LAVs have a significant Achilles’ heel: the potential for reversion to wt virulence. This risk is particularly acute for RNA viruses, which replicate without proofreading, resulting in an increased ability to revert to the wt sequence or restore virulence via compensatory mutations (pseudoreversion). However, altering virus fidelity can theoretically overcome this major drawback. This approach has only been examined with fidelity mutants of poliovirus and a low-fidelity ExoN mutant of SARS-CoV (69, 99). While the high fidelity poliovirus (69) and SARS-CoV ExoN (99) mutants both demonstrated increased immunogenicity and an improved safety profile compared to the parent viruses, this was not observed for the low-fidelity poliovirus (79). However, fidelity mutants have only been generated using wt virus strains, which are unlikely to be sufficiently attenuated for vaccine use. We hypothesized that increasing the attenuation of a live-attenuated RNA virus vaccine by altering the RdRp fidelity would further improve its safety and efficacy. We addressed this by validating a series of low-fidelity mutations in a model system using the VEEV vaccine strain TC-83 to determine how this affects

the stability and attenuation. Serial passaging of TC-83 in the presence of 5FU identified 3 mutations in the RdRp, and validation showed that all three mutations were required to decrease virus replication fidelity. Additionally, we identified a 4x mutant that acted much like TC-83 3x, but showed no difference in diversity.

At present, there is no atomic resolution structure for an alphavirus RdRp, which limits our understanding of their mechanisms of fidelity alteration. However, all the mutations in the 3x mutant (G14R, E37G and A96T) were at the 5' end of the nsP4 gene, similar to the placement of the poliovirus (PV) high fidelity G64S and low-fidelity H273R substitution, which are both on the periphery of the RdRp protein rather than near the active site (67, 79, 354). For PV, the presence of the G64S mutation does not significantly alter the structure of the polymerase, but it does decrease the incorporation rate of new nucleotides (97, 355). In fact, the current theory is that this substitution simply stabilizes the polymerase rather than altering the active site. Alternatively, low-fidelity H273R PV decreases fidelity by favoring an open state of the RdRp, which decreases the duration of this fidelity checkpoint, thus increasing the likelihood of NTP misincorporation (98). The presence of the low-fidelity mutations outside of the predicted active domain of the TC-83 nsP4 gene suggests similar mechanisms might be at play, but confirmation will require an atomic resolution structure.

There are two manners in which low-fidelity mutants have been isolated, either by mutating residues found to alter fidelity in other viruses or by passaging virus in the presence of a nucleoside analog. Of the latter, three low-fidelity mutants have been identified that are resistance to at least one nucleoside analog (74, 83, 88). Our 3x and 4x fidelity mutants appear to act similarly to these low-fidelity viruses, with resistance to 5FU, but not ribavirin. When examining the mutation frequency of different mutations, the fidelity mutants produced a much lower amount of U to C transition mutations during passage 1, which would be one of the mutations expected to be selected against during 5FU passaging. This also may explain why the mutants are most resistant to 5FU when

using moderate amounts of the nucleoside analog, but then increase in susceptibility again at higher concentrations, as there is no difference in the other uracil mutation frequencies. It would be interesting to test the passage 3 U4.4 and Vero viruses to re-examine 5FU resistance, as the frequency of U to C mutations increased during U4.4 cell passaging, but not Vero cell passaged. If the decreased U-C mutation frequency is playing a role in 5FU resistance, the U4.4 passaged virus is likely to have lost any 5FU resistance.

TC-83 3x is likely a low-fidelity mutant, as evidenced by the phenotypic tests, as well as the increased genetic diversity observed using Illumina sequencing during passages 1 and 3. The 4x mutant, while exhibiting phenotypic similarities with other altered fidelity mutants, had no significant difference in virus diversity compared to the TC-83 parent, even after multiple cell culture passages. Attenuation for this RdRp mutant may be due to slightly reduced growth kinetics (Figure 2.9A), but this slight reduction is commonly observed for fidelity mutants (67, 72, 74, 76, 77, 82, 85), suggesting another mechanism. This mutant needs to be further explored to determine mechanisms of attenuation.

Also of interest is the C488Y substitution that increased replication fidelity in CHIKV, but did not affect TC-83 fidelity, although it did attenuate TC-83 in the infant mouse model. This finding is the opposite of the outcome for SINV, which exhibited low-fidelity features when a low-fidelity CHIKV mutation was inserted (82). However, SINV is more closely related to CHIKV than VEEV, so this may explain why the effects did not transfer to TC-83 even though the residue is highly conserved among alphaviruses (80).

As the TC-83 3x virus stock was passaged, differences in diversity became more apparent, suggesting that the low-fidelity phenotype is slight, but stable for this virus and increases over multiple growth cycles. Interestingly, when total genome diversity was analyzed for each construct after 1 cell culture passage, there was no significant

difference in diversity when comparing cell types. This is in contradiction to the low-fidelity CHIKV mutants, which only showed increased diversity in vertebrate, but not in mosquito cells (82). However, while no significant difference was observed in overall diversity between the cell types, TC-83 3x produced much higher peaks in diversity in C7/10 cells than was observed in other cell types or viruses. This is intriguing, because it is hypothesized that mosquitoes are drivers of diversity, likely due to the sequence specificity of the mosquito antiviral RNAi response (i.e. siRNAs), although this has only been demonstrated for West Nile virus (277, 356-358). This hypothesis does not appear to explain the increased diversity observed during the TC-83 3x C7/10 passages, because these cells lack a functional siRNA response. Additionally, no increased hotspots were observed for U4.4 cells, which do produce antiviral siRNAs. Further work is needed to determine how these diversity hotspots correspond to small RNA targeting in mosquito cells and examine the effects of the host immune response on virus populations.

Illumina sequencing uncovered many noteworthy effects during RdRp mutant growth *in vitro*. In particular, many of the minority variant hotspots were conserved for TC-83 and the 3x and 4x mutants, although the amplitude of each peak was not. Interestingly, this mutation conservation was generally conserved up to 3 passages PE, although genetic drift likely accounted for approximately 50% of the high frequency minority variants by the third passage, suggesting that further passage would lead to further diversification. Also of interest were the E1 diversity peaks identified in TC-83, but to a much less extent for the RdRp mutants. These peaks were also found in the EP stock, but greatly increased after 1 passage, and then decreased again by 3 passages. The E1 glycoprotein is responsible for the uncoating of the virus particle and escape of the genome into the cytosol. Some substitutions in the CHIKV E1 glycoprotein have been found to increase vector infectivity and transmission (28, 129, 359). Diversity in this region may be important for increased vector fitness and/or host jumps.

As our study was designed to evaluate the effectiveness of RdRp mutations that decrease fidelity in vaccines, the mutants were put through a standard challenge model previously used for different VEEV vaccines (315, 316). Mice showed no adverse effects from vaccination, viremia was consistent with that expected for TC-83, and all mice were protected against lethal challenge. Additionally, the mutants induced higher antibody titers than TC-83. Our current hypothesis for this observation is that the low-fidelity RdRp creates an increased number of defective interfering (DI) virus particles, which are well known to be strong immune stimulators (360-363). As VEEV first replicates in the draining lymph node (222), the presence of these DI particles may restrict dissemination from the draining lymph node, allowing for a greater opportunity for antigen presentation and therefore an increased immune response. This needs to be explored in future work, perhaps by labeling each virus with luciferase and imaging infected mice to determine if delayed dissemination occurs, as well as where this delay occurs.

Finally, as previous studies have shown that high fidelity PV mutations cause attenuation in mouse models by reducing dissemination to the CNS (67-69), we tested our mutants in a lethal mouse model for TC-83. The 3x and 4x RdRp mutants initially displayed equivalent virulence to parent TC-83 when injected into a single tissue that can cause lethal damage (brain) and reduced virulence when injected via a multi-tissue model (SC). However, when this experiment was repeated with virus rescued from different EP stocks, using slightly different TC-83 backbones, the 3x and 4x mutants displayed greatly increased in virulence compared to the initial SC outcome. As *in vitro* transcription is known to be error-prone (101), this suggests that minority variants randomly generated during the transcription preceding EP can have large effects on the overall virus population health, and thus virulence. Importantly, the RdRp mutants were never significantly more virulent than TC-83 when injected SC. While TC-83 is not lethal in an adult mouse model, it would be interesting to determine if the 3x and 4x mutants have consistently delayed and/or decreased dissemination compared to wt virus. This would

allow for a greater understanding of how a low-fidelity TC-83 vaccine would operate in a fully immunocompetent host.

Here, we demonstrated that the presence of low-fidelity mutations in a LAV resulted in reduced or equal virulence in an infant mouse model and increased immunogenicity in an adult mouse model, both of which are desirable properties for LAVs. However, we also observed different outcomes in low-fidelity mutant attenuation *in vivo* when different pools of virus stock were used, suggesting that the low-fidelity virus population might not be initially stable. This demonstrates that there is great need to understand the role that minority variants play in phenotypic changes in vaccine development, as changes in the mutant spectrum may significantly alter the phenotype of vaccines.

Figure 2.1: *In vitro* characterization of the TC-83 RdRp mutants.

A schematic of the TC-83 genome showing the placement of the four mutations in the RdRp gene (A). Growth curves of TC-83 and the RdRp mutants in interferon negative Vero cells (B) or interferon competent HEK-293 cells (C). Experiments were performed in triplicate and titers were determined by standard plaque assay. Two-way ANOVA was used to determine statistical significance, and bars indicate standard deviation. Resistance of TC-83 mutants to treatment by 5FU (D). Cells were treated with 0, 10, 25, 50, 100, 200, or 300 µg/ml of 5FU and infected using an MOI of 0.01; all experiments were performed in triplicate. Samples were titrated by standard plaque assay. Statistical differences were determined by two-way ANOVA, and significance is detailed in the text. Resistance of TC-83 mutants to treatment by Ribavirin (E). Cells were treated with 0, 50, 100, 200, 300, or 400 µM Ribavirin and infected using an MOI of 0.01; all experiments were performed in triplicate. Samples were titrated by standard plaque assay. Statistical differences were determined by two-way ANOVA, and significance is detailed in the text.

A representative replicate is pictured for each virus isolate from each cell type. TC-83 (A, B), TC-83 3x (C, D), and TC-83 4x (E, F), U4.4 (A, C, E), Vero (B, D, F). Genome organization is color-coded using the following: nsP1: blue, nsP2: red, nsP3: green, nsP4: purple, capsid: orange, E3: black, E2: gold, 6k: navy blue, and E1: maroon.

Figure 2.8: Weight change, immunogenicity, and survival following vaccination and challenge.

Five-week old mice were injected with 10^5 PFU of TC-83, 3x, 4x, or mock in a 50ul volume (n=8 per vaccine treatment). Mice were monitored daily for percent weight change from the original weight at D0 (A). The effectiveness of the vaccine was determined by neutralizing antibody titer using serum from 6 weeks post-vaccination (B), and statistical differences were determined by two-way ANOVA, where $p < 0.01$ is represented by **. Mice were challenged with 10^5 PFU of VEEV strain 3908 and were monitored for percent weight change from the original weight at D0 (C) and survival (D).

	Day 1		Day 2		Day 3	
	No. positive	Average Titer (\pm standard deviation)	No. positive	Average Titer (\pm standard deviation)	No. positive	Average Titer (\pm standard deviation)
TC-83 3x	5/5	2.68 (\pm 0.52)	2/5	2.28 (\pm 0.21)	3/5	2.12 (\pm 0)
TC-83 4x	3/5	2.59 (\pm 0.41)	0/5	0	3/5	2.61 (\pm 0.59)
TC-83	4/5	2.94 (\pm 0.57)	1/5	2.73 (\pm 0)	2/5	2.47 (\pm 0.49)
PBS	0/5	0	0/5	0	0/5	0

Table 2.1: Viremia titers following vaccination with TC-83, TC-83 3x, TC-83 4x, or mock.

Different cages of vaccinated mice (n=5) were bled on alternating days.

TC-83 767	TC-83 pVE IC-92	TC-83 3X	TC-83 4X
401G	401C	401G	401G

11404T	11404T+T	11404T	11404T

Table 2.2: RdRp mutant TC-83 clone chimerization.

TC-83 3x and 4x were found to be chimeras of two different TC-83 clones in the lab: TC-83 767 and TC-83 pVE IC-92. The blue and red highlights indicate the mutations each RdRp mutant shares with one of the TC-83 clones. Mutations were synonymous, except for the T10356C mutation, which changes the amino acid from alanine to valine. For all of the experiments in this dissertation, TC-83 pVE IC-92 was used as the control TC-83.

Figure 2.9: Low-fidelity TC-83 3x variation in attenuation.

2-step growth curve in Vero cells using virus stock from clones containing the RdRp mutations in the control TC-83 backbone (A). Statistical differences were determined two-way ANOVA and are detailed in the text. Survival curves for the TC-83 mutants in 6-day old CD-1 mice following IC injection (B) and SC injection (C) of 10^5 PFU from RdRp EP stocks. “Old” denotes the original RdRp mutant clone, while “New” denotes RdRp mutants in the same backbone as the control TC-83. Statistical differences were determined using Kaplan-Meier tests and are detailed in the text.

LOW-FIDELITY TC-83 FITNESS IN THE MOSQUITO VECTOR

Chapter 3: Low-fidelity TC-83 is attenuated in the mosquito

INTRODUCTION

VEEV has been isolated from many species of mosquito, with confirmed enzootic vectors including various species of *Cu. (Mel.)* (255-259), as well as *Ps. confinnis* (252), *Ae. sollicitans* (252, 253), and *Ae. taeniorhynchus* (253, 254) during epizootic transmission. During epizootic infection, decades-old studies have found equine viremia titers to range from $10^5 - 10^8$ SMicLD₅₀/mL (364-366). SMicLD₅₀/mL is estimated to be approximately 50-850 times more sensitive than plaque assays for virulent VEEV strains (341, 365), although there is very little difference between PFU/mL and SMicLD₅₀/mL for TC-83 (365, 366). In horses vaccinated with TC-83, approximately 60-100% of horses produce low titer viremia, ranging from trace amounts (i.e. some suckling mice become sick but recover) to 3.7 SMicLD₅₀/mL (364-366).

Although these titers are low, TC-83 has been isolated from field-caught mosquitoes (306), suggesting that the vaccine is able to enter a transmission cycle. This is especially concerning due to the high levels of TC-83 reversion and pseudoreversion (292, 295), which could potentially initiate an epizootic outbreak. As our low-fidelity TC-83 3x mutant produces identical viremias post-vaccination of mice in comparison to TC-83, it is important to know if this mutant is more restricted in the mosquito vector than the original TC-83. As other arbovirus fidelity mutants are attenuated *in vitro* and *in vivo* in the mosquito (80, 82, 83), we hypothesize that TC-83 3x will be more attenuated than TC-83 in the mosquito vector.

METHODS

Cell cultures

Vero (African green monkey kidney) cells were obtained from the American Type Culture Collection (Bethesda, MD) and maintained in DMEM (Gibco) supplemented with 10% Fetal Bovine serum (FBS, Atlanta Biologicals), and 500µg/mL gentamycin (Corning) in a 37°C 5% CO₂ incubator. C7/10 and C6/36 mosquito cells were maintained in DMEM supplemented with 10% Fetal Bovine serum, 1% Minimal Essential Medium Nonessential Amino Acids (Gibco), 1% Trypose Phosphate Broth (Sigma), and 500µg/mL gentamycin in a 30°C 5% CO₂ incubator. U4.4 cells were maintained in Mitsunashi and Maramorosch media (Sigma) supplemented with 20% FBS, 2% Sodium Bicarbonate (7.5%) (Gibco), and 500µg/mL gentamycin in a 30°C 5% CO₂ incubator.

Plaque assay

One day prior to infection, 6-well or 12-well Vero plates were plated using 250,000 or 500,000 cells per well respectively to ensure approximately 90% confluency the following day. Virus stocks were diluted 1:10 8 times using 225µL DMEM (supplemented with 2% FBS and gentamycin) and 25µL virus. If no plaques were observed for an isolate, then the plaque assay was repeated using 100 µL of undiluted sample, resulting in a limit of detection of 10 PFU/mL. This dilution series was either performed using 1.5mL tubes (using vortexing to mix) or 96 well plates (using pipetting to mix). Media was then decanted from a cell culture plate and 100µL (12-well plate) or 200µL (6-well plate) of each dilution was added to a well. This was performed in duplicate. The infected monolayers were stored in a 37°C 5% CO₂ incubator for 1 hour and were gently shaken every 15 minutes to ensure an even infection distribution. After this incubation, a 0.4% agarose overlay (1 part 2% agarose (Lonza) in filter-purified water to 4 parts DMEM supplemented with 2%FBS and gentamycin) was added to each well, and the plates were returned to the incubator. Following a 48 hour incubation, the monolayers were fixed for 30 minutes using 10% formaldehyde (Fisherbrand) before the

agarose plugs were removed and the monolayer was stained with 0.25% crystal violet solution (Fisherbrand). The plates were then washed with water and allowed to dry before plaques were counted.

PFU per mL was calculated using the following formula: $\text{PFU/mL} = (\text{dilution} \times \text{number of plaques}) / (1000 / \text{amount plated})$, with “dilution” equaling the dilution at which the plaques were counted and “amount plated” equaling the amount of virus added when infecting the cells (i.e. 100 μ L for 12-well plates and 200 μ L for 6-well plates).

Mosquito infections

F1 generation *Ae. taeniorhynchus* mosquitoes were infected with TC-83 or TC-83 3x mixed 1:1 with defibrinated sheep blood (Colorado Serum Co.) to a final titer of 10⁵ PFU/mL in 4mL total. *Ae. sollicitans* mosquitoes also from a UTMB insectary colony were infected with TC-83 or TC-83 3x mixed 1:1 with defibrinated sheep blood to a final titer of 10⁷ PFU/mL in 4mL total.

2-3 mL of the virus/blood mixture was pipetted into a Hemotek reservoir enclosed in mouse skin. Two cohorts of 50 mosquitoes per virus were allowed to feed for 30 minutes before being transferred to a -20°C freezer until paralyzed. Mosquitoes that had failed to feed were discarded. Those that fed were incubated for 9 (*Ae. sollicitans*) or 10 (*Ae. taeniorhynchus*) days at 27°C before being harvested. Heads and bodies were removed and stored in separate tubes containing a steel bead as well as 125 μ L DMEM supplemented with 10% FBS, gentamycin, and 0.25 μ g/mL fungizone (Gibco). Mosquitoes were homogenized using a TissueLyser II (Qiagen) for 5 minutes at 26 beats/second, and then centrifuged for 5 minutes at 3.3 X g. Supernatant was transferred to a fresh tube and stored at -80°C. Plaque assays were used to determine virus titer.

Growth Curves

The day of the infection, U4.4 or C7/10 mosquito cells were counted using a hemocytometer and diluted to 10^6 cells/mL. Depending on the number of samples needed for each experimental condition, a certain volume of the cells was aliquoted into a 50mL tube with a single tube for each condition.

The cells were centrifuged for 2 minutes at $783 \times g$ and 4°C . Media was decanted, and the cells were infected with an MOI of 10 or 0.01 by resuspension in 500 μL of the appropriate media for the cell type (see “cell cultures”). The infected cells were incubated for one hour in a 30°C 5% CO_2 incubator with gentle mixing every 10 minutes. After this, the cells were centrifuged for 2 minutes at $783 \times g$ and 4°C and the inoculum was aspirated from the pellet and discarded. Following this, the cells were resuspended in 5mL of PBS and centrifuged for 2 minutes at $783 \times g$ and 4°C . After this wash step was repeated, the cells were resuspended in the initial volume of media and 0.5mL/well was aliquoted into a 24-well plate and returned to the 30°C 5% CO_2 incubator.

Virus was harvested by removing the entirety of the medium from three wells per time point (independent measures). During the dependent measures growth curve, media was replaced after each harvest. Harvested virus was supplemented with FBS to a final concentration of 20%, and clarified by centrifugation at $0.8 \times g$ for 5 min. The supernatant was transferred to a new tube and stored at -80°C . Viral titers were determined by plaque assays on Vero cells, as described above.

Enoxacin treatment of mosquito cells

The day of the infection, media was removed from T-150 flasks of U4.4 or C6/36 mosquito cells and replaced with the 15mL of the appropriate media for the cell type (see “cell cultures”) supplemented with 25 or 50 μM Enoxacin (Sigma). After a 2 hour incubation in a 30°C 5% CO_2 incubator, the cells were counted using a hemocytometer and diluted to 10^6 cells/mL. Depending on the number of samples needed for each

experimental condition, a certain volume of the cells was aliquoted into a 50mL tube with a single tube for each condition.

The cells were centrifuged for 2 minutes at $783 \times g$ and 4°C . Media was decanted, and the cells were infected with an MOI of 10 or 0.01 by resuspension in 500 μL of the appropriate media for the cell type. The infected cells were incubated for one hour in a 30°C 5% CO_2 incubator with gentle mixing every 10 minutes. After this, the cells were centrifuged for 2 minutes at $783 \times g$ and 4°C and the inoculum was aspirated from the pellet and discarded. Following this, the cells were resuspended in 5mL of PBS and centrifuged for 2 minutes at $783 \times g$ and 4°C . After this wash step was repeated, the cells were resuspended in the initial volume of media supplemented with 25 or 50 μM Enoxacin. 0.5mL of this cellular suspension was aliquoted into a 24-well plate and returned to the 30°C 5% CO_2 incubator.

Virus was harvested by removing the entirety of the medium from three wells per time point. Harvested virus was supplemented with FBS to a final concentration of 20%, and clarified by centrifugation at $0.8 \times g$ for 5 min. The supernatant was transferred to a new tube and stored at -80°C . Viral titers were determined by plaque assays.

Sanger sequencing of TC-83 RdRp mutations

To determine if the TC-83 3x virus that was able to grow well during the 2-step mosquito cells growth curve may have reverted any of the RdRp mutations, sequencing was performed.

Virus RNA was extracted from the positive virus samples using the QIAamp Viral RNA Minikit as per the manufacturer's protocol and stored at -80°C . Using 3 μL of this RNA, the Superscript III RT PCR kit (Invitrogen) was used to generate cDNA by adding 5 μL nuclease-free water, 1 μL dNTPs (NEB), and 1 μL random hexamers. This was incubated at 65°C for 5 minutes and placed on ice for 2 minutes. Following these incubations, 4 μL MgCl_2 , 2 μL 10X RT buffer, 2 μL DTT, 1 μL RNase OUT, and 1 μL SSIII

enzyme was added to the first tube and incubated for 10 minutes at room temperature, followed by 43°C for 90 minutes, and finally 50°C for 10 minutes. This was stored at -20°C.

High fidelity Phusion PCR (NEB) was used to generate approximately two, 1.5kb amplicons that encompassed the RdRp mutations. In a PCR tube, 2.5µl of cDNA was added to 10µl 5X buffer, 1µl dNTPs, 1µl forward primer (20µM), 1µl reverse primer (20µM), 32µl nuclease-free water, 2µl MgCl₂, and 0.5µl Phusion polymerase. The amplicon primers were as follows: 4937V+6579C and 6207V+7800C. The PCRs were amplified using a 98°C hot start for 30 seconds, followed by 35 cycles of a 10 second, 98°C denaturation, a 10 second 60°C anneal, and a 1.5 minute elongation at 72°C.

Following PCR amplification, amplicons were visualized by running the entire contents of the reaction on a 1% agarose gel in TAE buffer. The bands were excised and purified using the QIAquick Gel Extraction kit as per the manufacturer's protocol. DNA was eluted into 35µl of nuclease-free water and stored at -20°C.

Sequencing reactions were prepared by adding 1µL of a 2µM primer (4937V, 5200C, 5500V, 5750C, 6000V, or 6579C for the first amplicon and 6207V, 6750V, 7000C, 7250V, or 7800C for the second amplicon) (Table 3.1) to 5µL DNA, 2µL 5X sequencing buffer, and 2µL BigDye (Applied Biosystems). The sequencing reactions were amplified using a 96°C hot start for 2 minutes, followed by 30 cycles of a 10 second 96°C denaturation, a 5 second 50°C anneal, and a 4 minute elongation at 60°C. Following this, sequencing reactions were purified using Performa spin columns (EdgeBio) as per the manufacturer's protocol, and loaded onto the Applied Biosystems 3500 Genetic Analyzer sequencer. Sequences were analyzed using Sequencher version 5.0.1.

RESULTS

Mosquitoes are refractory to TC-83 infection

Although TC-83 was previously isolated from a pool of field-caught *Ps. confinnis* mosquitoes (306), these mosquitoes were not available for infection. Instead, other VEEV vectors were tested for susceptibility to TC-83.

First, *Ae. taeniorhynchus* mosquitoes were allowed to feed on a blood meal spiked with 10^5 PFU/mL of TC-83 or TC-83 3x (Appendix 2, stocks 1-2). Of the 100 mosquitoes allowed to feed per virus, approximately half of these mosquitoes became engorged. After a 10-day incubation, however, none of the mosquitoes that survived were positive for infection as measured by CPE assay on Vero cells (data not shown).

Later, *Ae. sollicitans* mosquitoes were allowed to blood feed using a higher dose of 10^7 PFU/mL (Appendix 2, stocks 4-5). Of the approximately 100 mosquitoes that were allowed to feed per virus (Table 3.2), roughly half of the mosquitoes became engorged, and 23 (TC-83) or 18 (TC-83 3x) survived the 9-day incubation period. Of these, only 4 mosquitoes became infected per virus, with one or two mosquitoes experiencing a disseminated infection. There was no significant difference in the body or head titers of the TC-83 or TC-83 3x infected mosquitoes (Figure 3.1).

Attenuated growth of low-fidelity TC-83 *in vitro*

Due to the high number of mosquito infections that would be required to further study infection *in vivo*, as well as the unnaturally high titers required for infection, *in vitro* studies were carried out to further determine differences in the mosquito host between TC-83 and the low-fidelity TC-83 3x.

One-step growth curves were performed in various mosquito cells to determine differences in the single-cell life cycle kinetics of the viruses (Figure 3.2). As expected, TC-83 was able to grow to higher titers in C6/36 and C7/10 cells, which lack a functional siRNA pathway, than in U4.4 mosquito cells, which produce antiviral siRNAs (272) (Figure 3.2 A-D). We hypothesized that these siRNAs would play a role in attenuating low-fidelity TC-83 due to the sequence specificity of RNAi. Interestingly, TC-83 3x was

attenuated in all of the tested mosquito cells. These results were repeatable (Figure 3.2A-B (Appendix 2, stocks 1-2) versus Figure 3.2C-D (Appendix 2, stocks 1-2). The observed attenuation of TC-83 3x was not due to the RdRp mutations altering temperature sensitivity, as Vero cells infected with TC-83 or TC-83 3x at 30°C showed no significant differences in virus titer (Figure 3.2 E-F, Appendix 2 stocks 8-9).

During 2-step growth curves, which measure differences in growth kinetics that may need several lifecycles to become apparent, TC-83 growth was slightly, but not significantly attenuated in U4.4 versus C7/10 mosquito cells. The low-fidelity mutant, however, struggled to produce infectious virus, with many isolates measuring completely negative by standard plaque assay. Independent samples were taken for each time point, so samples negative for infectious virus resulted in very large error bars (Figure 3.3A, Appendix 2 stocks 1-2). When these virus negative samples were removed (Figure 3.3 B), the growth kinetics more closely reflected the 1-step growth curve results (Figure 3.2 A&C). Sanger sequencing of successful TC-83 3x virus showed that none of fidelity-altering mutations reverted.

To determine if the virus extinction results in Figure 3.3 were due to fluctuating release of the virus or an overall failure of the infecting virus to cause a productive infection, 2-step growth curves were performed in parallel using 10 replicates of TC-83 3x per cell type. For this experiment, media was collected and replaced at every time point. In C7/10 cells (Figure 3.4A, Appendix 2 stocks 4-5), 4 of the 10 replicates did not produce any infectious virus as measured by plaque assays, while the remainder of the replicates all grew at a normal rate once virus began to be produced. The U4.4 replicates acted similarly to the C7/10 cell infection (Figure 3.4B). Interestingly, at 24 HPI the titer dipped for many of the U4.4 replicates, with the lowest-titer replicate driven to extinction by 48 HPI.

Unfortunately, efforts to better understand this attenuation were stalled when a new TC-83 3x EP stock failed to exhibit this attenuation phenotype, even after multiple

infections (data not shown, Appendix 2 stocks 9-10). As two prior EP stocks exhibited this attenuated phenotype (Appendix 2 stocks 2 and 5), this suggests that the *in vitro* mosquito cell attenuation results from the most EP recent stock are the exception rather than the norm.

Enoxacin treatment has no effect on TC-83 growth *in vitro*

Mosquito cells were treated with enoxacin, a fluoroquinolone shown to enhance the RNAi response (367, 368), to determine if enhancement of RNAi would further attenuate the low-fidelity TC-83 mutant. No effect was observed when cells were treated with 50 or 100 μ M enoxacin and infected with an MOI of 10 (Figure 3.5, Appendix 2 stocks 1-2).

When treated with 50 μ M enoxacin and infected with an MOI of 0.01 (Appendix 2, stocks 1-2), no difference was observed for untreated cells infected with TC-83 (Figure 3.6 A&C). The extreme differences in virus titer observed during low MOI TC-83 3x infection also occurred when cells were treated with enoxacin (Figure 3.6 A&C), with enoxacin perhaps contributing to a lack of virus growth in U4.4 cells (Figure 3.7).

DISCUSSION

For a mosquito to be considered an arbovirus vector, it must be known to interact with and take blood meals from the vertebrate host in question, have multiple mosquito isolates from nature that are positive for virus infection, and be experimentally demonstrated to be competent for infection and transmission (369, 370). Based upon this definition, TC-83 has not been proven to be transmissible by a mosquito vector, as it has only been isolated once in the wild (306) and mosquitoes are only easily infected via IT injection (371). Our *in vivo* results suggest that the probability of a natural mosquito infection with TC-83 is low. For example, although *Ae. sollicitans* mosquitoes typically

exhibit high VEEV infection rates (253), these mosquitoes were difficult to infect with TC-83 even when using bloodmeal titers 10,000-fold higher than those expected from a vaccinated horse (304, 366).

However, on the off chance that a mosquito does become infected with TC-83, our *in vitro* results suggest that the low-fidelity TC-83 mutant will be more attenuated in the vector than the original vaccine. This is not surprising as other fidelity arbovirus mutants are also attenuated in the mosquito vector (80, 82, 83). However, the mechanisms behind this attenuation are not well understood. A recent paper found low-fidelity SINV to be attenuated in *Drosophila* due to the increased number of defective viral genomes being produced during infection, causing increased stimulation of the RNAi response (372). Due to the similarities between this mutant and ours, it is likely that our low-fidelity mutant is also attenuated in a similar fashion.

Because RNAi does not play a significant antiviral role in the vertebrate host, where no difference between fidelity mutants and parent virus is observed *in vitro*, this suggests that RNAi is playing the predominant role in fidelity mutant attenuation in mosquito cells. As altering the virus fidelity changes the RNA sequences produced during virus replication, we hypothesized that the antiviral RNAi response in the mosquito was decreasing low-fidelity TC-83 3x replication fitness. To better understand if this response is why fidelity mutants are attenuated *in vitro* in mosquito cells, we attempted to enhance the RNAi response using the fluoroquinolone, enoxacin. In our hands, enoxacin did not appear to have any effect on virus growth for either TC-83 or TC-83 3x. This may be because enoxacin has only been previously examined in mammalian cells (367, 368), suggesting that the mechanism of action for this drug is not conserved in mosquitoes. Future work examining the small RNA repertoire in mosquito cells is needed to better understand the interaction of our low-fidelity virus with the RNAi response.

Primer name	Primer sequence (5' to 3')

Table 3.1: PCR and sequencing primers.

“V” designates primer sequences complementary to the virus sequence (i.e. positive-sense), while “C” designates primer sequences that bind to the minus-sense strand.

	TC-83	TC-83 3X
Number Fed/Total	47/96	57/101
Number Survived	23	18
CPE + Bodies	4	4
CPE + Heads	2	1

Table 3.2: *Ae. sollicitans* mosquito infection.

Ae sollicitans mosquitoes were allowed to feed on an infectious blood meal containing 10^7 PFU of TC-83 or TC-83 3x. Mosquitoes were harvested after 10 days, and CPE assays were used to determine infection status.

Figure 3.1: *Ae. sollicitans* body and head titers.

Ae. sollicitans mosquitoes were allowed to feed on an infectious blood meal containing 10^7 PFU of TC-83 or TC-83 3x. Mosquitoes were harvested after 10 days, and plaque assays were used to determine the body (A) and head (B) titers of CPE+ mosquitoes. Student's t-test found no significant differences in body titers.

Figure 3.2: Mosquito cell 1-step growth curves.

C6/36 and U4.4 mosquito cells were infected with an MOI of 10 of TC-83 or TC-83 3x (A, B). Repeat infection of C7/10 and U4.4 mosquito cells infected with an MOI of 10 of TC-83 or TC-83 3x (C, D). Vero cells infected with at MOI of 10 at 30C (E, F). Infections were performed in triplicate and plaque assayed in duplicate. Error bars show standard deviation. Two-way ANOVA was performed. Significance is displayed in B, D, and F. $p < 0.05$ designated by *, $p < 0.01$ designated by **, $p < 0.001$ designated by ***, $p < 0.0001$ designated by ****.

Figure 3.3: Mosquito cell 2-step growth curves.

U4.4 (A, B, C, D) and C7/10 (A, B, E, F) mosquito cells were infected with TC-83 or TC-83 3x using an MOI of 0.01. Many of the isolates were negative for infectious virus, resulting in large error bars (A, C, E). To better visualize the infectious titers produced, isolates negative for virus were removed (B, D, F). Plaque assays were performed in duplicate. Error bars show standard deviation.

Figure 3.4: Repeated measure TC-83 3x mosquito cell infection.

To determine how the virus titer changes over time in mosquito cells, C7/10 (A) and U4.4 (B) were infected in replicates of 10 using an MOI of 0.01. Plaque assays were performed in duplicate. Error bars show standard deviation.

Figure 3.5: Enoxacin does not protect mosquito cells against high MOI TC-83 infection. C6/36 cells infected with TC-83 (A) or TC-83 3x (B). U4.4 cells infected with TC-83 (C) or TC-83 3x (D). Mosquito cells were treated with enoxacin or mock, and infections were performed in triplicate using an MOI of 10. Plaque assays were performed in duplicate. Repeated measures ANOVA found no significant difference. Error bars show standard deviation.

Figure 3.6: Enoxacin treated mosquito cells during a low MOI infection.

U4.4 (A, B) and C7/10 (C, D) mosquito cells were treated with enoxacin or mock and infected with TC-83 or TC-83 3x using an MOI of 0.01. Many of the isolates were negative for infectious virus, resulting in large error bars (A, C). To better visualize the infectious titers produced, isolates negative for virus were removed (B, D). Plaque assays were performed in duplicate. Error bars show standard deviation.

Figure 3.7: Percentage of virus extinctions in mosquito cells.

During 2-step C7/10 and U4.4 mosquito cell growth curves, a significant number of TC-83 3x infected cells failed to produce infectious virus.

VACCINE STABILITY

Chapter 4: Low-fidelity TC-83 genetic and phenotypic stability²

INTRODUCTION

Although LAVs are immunogenic and relatively easy to manufacture, there is the potential for reversion and restoration of virulence. Unfortunately, due to their error-prone RdRp (7), RNA virus LAVs carry the highest risk of reversion or pseudoreversion. For example, the global eradication of PV is nearly complete, largely due to the success of the live-attenuated Sabin vaccine (373). However, this vaccine has also been the source of sporadic cases of vaccine-derived polio, which occasionally result in outbreaks (373-376). Recombination with other enteroviruses (374, 376) and back-mutations (374, 375) of the attenuating mutations have both been described as mechanisms for this reversion, with low vaccination coverage increasing this risk (373). Due to stability issues such as these, as well as the ever-increasing threshold for what constitutes a safe vaccine, it is highly important to test LAVs for their genetic and phenotypic stability. As our RdRp mutant is low-fidelity, it is even more critical to closely examine and determine if this vaccine candidate is at higher risk of reversion compared to TC-83, which itself is notoriously unstable and known to rapidly increase in virulence (292, 295).

While some previously described low-fidelity mutants, such as the alphaviruses CHIKV and SINV, have been shown to be prone to reversion (82), other low-fidelity mutants, such as the ExoN mutant of SARS-CoV are quite stable (99). The mechanisms behind this difference in stability are unknown, although it may be due to the number of

² Content of this chapter has previously been published: Kautz TF, Guerbois M, Khanipov K, Patterson EI, Langsjoen RM, Yun R, et al. Low-fidelity Venezuelan equine encephalitis virus polymerase mutants to improve live-attenuated vaccine safety and efficacy. *Virus Evolution*, 4(1), vey004. Reproduced with permission.

fidelity altering mutations; CHIKV and SINV are only one mutation away from reversion, while the SARS-CoV ExoN mutant is six mutations away. As low-fidelity TC-83 exhibited unstable phenotypes in the studies described in the previous two chapters, we hypothesize that the likelihood of reversion or pseudoreversion is rather high, much like the low-fidelity CHIKV and SINV mutants. During this aim, genetic stability (i.e. reversion of the TC-83 attenuating mutations and/or low-fidelity mutations) was measured *in vitro* and *in vivo*, while changes in virulence were assessed *in vivo*.

METHODS

Cell culture

Vero (African green monkey kidney), HEK-293 (human embryonic kidney), MRC-5 (human fetal lung fibroblast), and Baby Hamster Kidney (BHK) cells were obtained from the American Type Culture Collection (ATCC) (Bethesda, MD) and maintained in DMEM (Gibco) supplemented with 10% Fetal Bovine serum (FBS, Atlanta Biologicals), and 500µg/mL gentamycin (Corning) in a 37°C 5% CO₂ incubator. C7/10 cells were maintained in DMEM supplemented with 10% Fetal Bovine serum, 1% Minimal Essential Medium Nonessential Amino Acids (Gibco), 1% Trypose Phosphate Broth (Sigma), and 500µg/mL gentamycin in a 30°C 5% CO₂ incubator. U4.4 cells were maintained in Mitsuhashi and Maramorosch media (Sigma) supplemented with 20% FBS, 2% Sodium Bicarbonate (7.5%) (Gibco), and 500µg/mL gentamycin in a 30°C 5% CO₂ incubator.

Virus stock generation

Viruses were rescued from a TC-83 infectious clone (307) by electroporation using BHK cells. First, 5µg of TC-83 or the other RdRp mutants was linearized using the restriction enzyme MluI (NEB) in a 50µL volume. 5µL of each digestion was mixed with 1µL 6el loading dye (NEB) and run on a 1% agarose (GeneMate) TAE (Fisherbrand) gel

at ca. 100V for ca. 1 hour to confirm digestion. The remainder of the linearized product was purified using a NucleoSpin PCR Clean-up and Gel Extraction kit (Clontech) as per the manufacturer's protocol.

In vitro transcription of the linearized DNA was performed in a 26 μ L volume using 2.5 μ L DTT (Invitrogen), 5 μ L 10X transcription buffer (Ambion), 2.5 μ L 10mM cap (NEB), 2.5 μ L 10mM rNTP (Roche), 250ng linearized DNA, X μ L nuclease-free water up to a final volume of 26 μ L, 0.5 μ L RNaseOUT (Invitrogen), and 1 μ L of T7 (Ambion) (TC-83) or SP6 polymerase (Ambion) (RdRp mutants for mouse passaging and *in vitro* transmission cycle passaging). This was incubated for 1 hour at 37°C and stored at -20°C overnight.

BHK cells were grown overnight in a T-150 flask to approximately 95% confluency the next day using complete media (DMEM supplemented with 10% FBS, 1% Minimal Essential Medium Nonessential Amino Acids, 1mM Sodium Pyruvate (Corning), and gentamycin. After one wash with with PBS (Gibco), 0.05% trypsin-EDTA (Corning) was used to detach the cells from the flask. Once detached, 4mL of complete media was added to the cells, and this was transferred to a 15mL conical tube and pelleted for 5 minutes at 125 X g. The media was decanted and the cells were resuspended in 7mL of cold PBS. This was wash repeated twice. Finally, the cells were resuspended in 450 μ L of cold PBS and stored on ice until added to 5 μ L of RNA from the *in vitro* transcription. This was gently mixed before being transferred to an electroporation cuvette with a 2mm gap (Fisherbrand). The sample was electroporated using a BTX 830 machine under the following conditions: 510V, 100 μ s pulse, 5 pulses, 184ms interval. The cuvette was left for 10 minutes at room temperature before the cells were transferred to a T-75 flask with 10mL of complete media and stored in a 37°C 5% CO₂ incubator. To collect, the supernatant from the flask was added to 2mL of FBS. The flask was then returned to the incubator after rehydrating the cells with fresh complete media. The supernatant was then clarified by centrifugation at 783 X g for 5 minutes at

4°C before being transferred to new 1.5mL tubes and finally stored at -80°C. Titters of the EP stock virus were determined by plaque assay using Vero cells.

Plaque assay

One day prior to infection, 6-well or 12-well Vero plates were plated using 250,000 or 500,000 cells per well respectively to ensure approximately 90% confluency the following day. Virus stocks were diluted 1:10 8 times using 225µL DMEM (supplemented with 2% FBS and gentamycin) and 25µL virus. This dilution series was either performed using 1.5mL tubes (using vortexing to mix) or 96 well plates (using pipetting to mix). Media was then decanted from a cell culture plate and 100µL (12-well plate) or 200µL (6-well plate) of each dilution was added to a well. This was performed in duplicate. The infected monolayers were stored in a 37°C 5% CO₂ incubator for 1 hour and were gently shaken every 15 minutes to ensure an even infection distribution. After this incubation, a 0.4% agarose overlay (1 part 2% agarose (Lonza) in filter-purified water to 4 parts DMEM supplemented with 2%FBS and gentamycin) was added to each well, and the plates were returned to the incubator. Following a 48 hour incubation, the monolayers were fixed for 30 minutes using 10% formaldehyde (Fisherbrand) before the agarose plugs were removed and the monolayer was stained with 0.25% crystal violet solution (Fisherbrand). The plates were then washed with water and allowed to dry before plaques were counted.

PFU per mL was calculated using the following formula: $\text{PFU/mL} = (\text{dilution} \times \text{number of plaques}) / (1000 / \text{amount plated})$, with “dilution” equaling the dilution at which the plaques were counted and “amount plated” equaling the amount of virus added when infecting the cells (i.e. 100µL for 12-well plates and 200µL for 6-well plates).

Illumina NGS for EP stock generation and mouse passaging

VIRAL RNA EXTRACTION

Viral RNA was extracted using the Qiagen viral RNA mini kit as per the manufacturer's protocol.

LIBRARY PREPARATION

Illumina sequencing was performed by the UTMB sequencing core. Viral RNA from cell culture extracts were fragmented by incubation at 94°C for 8 minutes in 19.5 µl of fragmentation buffer (Illumina, San Diego, CA). First and second strand synthesis, adapter ligation, and amplification of the library were performed using the Illumina TruSeq RNA Sample Preparation kit as per the manufacturer's protocol. For virus isolates from animals, PCR was first done using sequence-specific primers tiled across the VEEV genome to provide amplified products of approximately 1.5kb in size that were used for library generation. Products were fragmented using transposons, then adapter ligation and amplification of the library was performed using the Illumina TruSeq RNA Sample Preparation kit under conditions described by the manufacturer (Illumina, San Diego, CA). Samples were tracked using the "index tags" incorporated into the adapters as defined by the manufacturer.

Sequence assembly and analysis

Illumina sequencing analysis was performed by the Fofanov lab at UTMB.

QUALITY AND FILTRATION

The quality for each sample/dataset was assessed using FASTQC (351). The paired-end reads were merged for each sample and then filtered to exclude reads with unknown characters (anything other than A, T, C, G) and low quality (<15 quality score), so that only high quality reads were used during analysis. Additionally, the first 16 bases of each read were trimmed due to nucleotide bias.

REFERENCE SEQUENCE

The analysis was performed using VEEV strain TC-83, complete genome (GenBank accession #: L01443.1) (308).

VIRUS DIVERSITY ANALYSIS

To analyze the variant hotspots, each sample was run through a novel rare variant pipeline (available upon request). The pipeline first maps each read to the reference VEEV genome with perfect match, then unmapped reads are re-mapped with 1 mismatch and added to the final map. The 34 base long reads used in the analyses were validated as viral sequences and not host sequences by analysis of the longest subsequences shared explicitly (no mismatches allowed) and longest similar (1 mismatch allowed) between viral and host genomes. Positions in which the number of reads mapped with mismatches was higher than perfectly mapped reads or coverage was below 100 were excluded from diversity calculations. Mutation frequency per sample was calculated by summing the per position diversities and normalizing by the number of positions for which diversity was calculated. Shannon Entropy was calculated using the equation $-\sum_i^s p \log(p)/N$, where p equals the probability of mutation and N equals the number of base calls that can happen at a position (i.e. A, G, C, T, insertion, or deletion).

Cloning

TC-83 GFP

TC-83 containing GFP under the control of a second subgenomic promoter was provided by the Weaver lab at UTMB (Figure 6.1C). TC-83 GFP and TC-83 3x were digested using the restriction enzymes PspOMI (NEB) and PpuMI (NEB) as per the manufacturer's protocol. The digestion was validated by running the entire contents of the digestion on a 1% agarose TAE gel. Bands were cut out and purified using the QIAquick Gel Extraction kit (Qiagen) as per the manufacturer's protocol. The TC-83

GFP genome containing the GFP gene was ligated with the TC-83 3x genome containing the RdRp mutations using a T4 DNA ligase kit (NEB) as per the manufacturer's protocol at a 1:3 insert to vector ratio. 4µL of the ligation was transformed using TOP10 competent cells (Invitrogen) as per the manufacturer's protocol, and 50µL of the transformation was plated on an LB-agar plate supplemented with 100µg/mL ampicillin and allowed to grow overnight in a 37°C incubator.

Colonies were picked the next morning and tested for GFP insertion using the GoTaq green PCR master mix (Promega) as per the manufacturer's protocol, with the primers 6705V (5'GCHGTCCTGCTTCCGAAC) and 7800C (5'CGTGGTTCTTCTTCTTCTTCC) used to determine GFP insertion. Of the colonies positive for the insert, one was used to spike 250mL of LB supplemented with 100µg/mL ampicillin. This was allowed to grow overnight in a 37°C incubator at 250rpm. The next morning, the bacteria were pelleted by centrifugation for 15 minutes at 2003 X g, and the plasmid was purified using a Plasmid Maxi kit (Qiagen). The purified plasmid stock was stored at -80°C.

TC-83 RT-qPCR CONTROL PLASMID

To determine RNA copy number, a control plasmid containing a portion of TC-83 complementary to the real time PCR primers was needed. TC-83 plasmid DNA and the pBluescript II (SK+) plasmid (Stratagene) were digested with XbaI (NEB) and BamHI (NEB) as per the manufacturer's protocol, generating an approximately 1.6kb fragment of TC-83 for insertion. The digestion was validated by running its entire contents on a 1% agarose TAE gel. Bands were cut out and purified using the QIAquick Gel Extraction kit (Qiagen) as per the manufacturer's protocol. The 1.6kb TC-83 genome fragment was ligated with the pBluescript II (SK+) plasmid using the T4 DNA ligase kit (NEB) as per the manufacturer's protocol and using a 1:3 insert to vector ratio. 4µL of the ligation was transformed using TOP10 competent cells (Invitrogen) as per the manufacturer's

protocol, and 50µL of the transformation was plated on an LB-agar plate (Fisherbrand) supplemented with 100µg/mL ampicillin (Sigma) and allowed to grow overnight in a 37°C incubator.

Colonies were picked the next morning and tested for TC-83 fragment insertion using the GoTaq green PCR master mix (Promega) as per the manufacturer's protocol. The primers M13 forward (5'GTAAAACGACGGCCAGT) and M13 reverse (5'CAGGAAACAGCTATGAC) primers were used to determine TC-83 insertion. Of the colonies positive for the insert, one was used to spike 250mL of LB supplemented with 100µg/mL ampicillin. This was allowed to grow overnight in a 37°C incubator at 250rpm. The next morning, the bacteria were pelleted by centrifugation for 15 minutes at 2003 X g, and the plasmid was purified using the NucleoBond Xtra Maxi Plus kit (Clontech). The purified plasmid stock was stored at -80°C.

RT-qPCR for TC-83 RNA copy number

COPY NUMBER STANDARD

To prepare the copy number standard (see "TC-83 RT-qPCR control plasmid"), 1µg of the plasmid was digested using SphI (NEB) according to the manufacturer's protocol. The digested plasmid was cleaned using the ClonTech PCR-cleanup kit as per the manufacturer's protocol, and transcribed using the MaxiScript T7 kit (Ambion), also using the manufacturer's protocol. Once transcribed, the plasmid DNA was digested using the DNA-free DNA removal kit (Invitrogen) and the RNA was further purified using the RNAqueous total RNA isolation kit (Ambion), both according to the manufacturer's protocol. Finally, linearization, transcription, DNase I treatment, and further purification of the copy number standard were visualized for confirmation of each step using a 1% agarose TAE gel. Copy number was calculated using a DS-11 spectrophotometer (DeNovix) to quantify the amount of RNA per microliter. An online calculator (<http://endmemo.com/bio/dnacopynum.php>) used this and the transcript length

(1,723bp) to determine the RNA copy number per microliter. Following this, the RNA was diluted to 2×10^{10} copies per μL in $20\mu\text{L}$ aliquots and stored in a cold block at -20°C . RNA was only freeze-thawed once before being discarded.

RT-qPCR

Viral RNA was extracted using the ZR Viral RNA minikit (Zymo) as per the manufacturer's protocol and eluted in $15\mu\text{L}$ nuclease free water. This was stored on ice as the rest of the reaction was prepared.

A standard curve of the above RNA standard was made to total 8, 10-fold dilutions in nuclease-free water ($5\mu\text{L}$ RNA mixed with $45\mu\text{L}$ nuclease-free water). Pipetting was used to mix between each dilution. This was stored on ice while the master mix was prepared.

Real time PCR primers were designed to amplify a portion of the nsP3 gene. The forward (4840F 5-ATG CCA TGA CTC CAG AAA GAG-3) and reverse (4981R 5-GGT GAG AAC AAT ATA GGC TGG G-3) primers were diluted to $20\mu\text{M}$ stocks in nuclease-free water, whereas the FAM tagged probe (4926P 5- /56-FAM/ ACT TCG GCA ATG GAA AGG ATG AGC A/3BHQ_1/ -3) was diluted to a $5\mu\text{M}$ stock, also in nuclease-free water. A master mix of reagents was made using $0.5\mu\text{L}$ of the 40X TaqMan RT enzyme, $10\mu\text{L}$ 2X RT-PCR mix, $0.9\mu\text{L}$ 4840F stock primer, $0.9\mu\text{L}$ 2981R stock primer, $1\mu\text{L}$ 4840F stock probe, and $1.7\mu\text{L}$ nuclease-free water per sample (TaqMan RNA-to Ct 1-Step kit, Applied Biosystems). This was vortexed to mix and stored on ice.

To set up the PCR, $10\mu\text{L}$ of viral RNA, standard, or nuclease-free water (as a non-template control) was added to each well in every other column of a 96-well Real Time PCR plate (Applied Biosystems). To this, $30\mu\text{L}$ of the above master mix was added, and a multichannel pipet was used to mix. After thorough mixing, $20\mu\text{L}$ from each well was transferred to the adjacent well and the plate was sealed with optical tape (Applied Biosystems). After the plate was centrifuged at $125 \times g$ for 1 minute, it was loaded into

the QuantStudio 6 Flex Real Time PCR System (Applied Biosystems), which was run using a 15 minute RT step at 48°C, followed by a 10 minute hot start at 95°C, and lastly 40 cycles consisting of a 15 second denaturation at 95°C and 1 minute annealing and elongation step at 60°C. Following the run, the copy number calculated using the RNA standard was converted to RNA copy number per mL.

TC-83 *in vitro* passaging: GFP

One day prior to infection, a 6-well plate was seeded with 500,000 Vero cells. The day of infection, TC-83 GFP or TC-83 3x GFP (low-fidelity TC-83) was diluted 10,000-fold for an MOI of approximately 0.5. Once diluted, media was decanted from the 6-well Vero cell plate and 200µL of diluted virus was used to infect each well. These infections were performed using three replicates per virus. After this, the plate was transferred to a 37°C 5% CO₂ incubator for 1 hour with occasional shaking. When the incubation was complete, the inoculum was removed and 2mL of DMEM supplemented with 2% FBS and gentamycin was added to each well. The plates were then returned to the 37°C 5% CO₂ incubator.

After a 24 hour incubation, the cell supernatant was removed and transferred to a tube with FBS to a final concentration of 20% FBS. This was centrifuged for 5 minutes at 0.8 X g and transferred to a new tube. These tubes were stored at -80°C. Plaque assays were used to determine virus titer. Ten total passages were performed.

To determine PFU:GFP, plaque assays were performed as per the usual protocol. After 48 hours, the cells were visualized under a fluorescent microscope and fluorescent plaques were counted. Following this, the cells were fixed and stained following the standard plaque assay protocol, and the number of plaques were counted. The number of GFP to PFU plaques was then calculated as a ratio to determine the amount of GFP fluorescence lost over the course of passaging.

Illumina NGS for GFP passaging

VIRAL RNA EXTRACTION

Viral RNA was extracted using the Zymo Direct-zol RNA mini kit as per the manufacturer's protocol. 100ng of RNA was used for each ClickSeq library.

CLICKSEQ LIBRARY PREPARATION

ClickSeq (65) was used instead of the traditional Illumina library procedures to avoid the errant recombination that frequently occurs during the typical fragmentation and ligation steps. Instead of RNA fragmentation, SSIII RT-PCR (Invitrogen) is performed using random hexamers attached to an Illumina p7 adapter sequence. In addition to this, azido-NTPs, which cause chain-termination, are added to the NTPs at a 1:35 ratio. In a manner similar to Sanger sequencing, this results in cDNA strands of various sizes. Following this, a modified 5'-hexynyl Illumina sequencing adapter was click-ligated onto the N-terminus of the cDNA strands using a copper-catalyzed azide-alkyne cycloaddition. The cDNA was then purified using a Zymo DNA clean column and amplified using 18 cycles of OneTaq (NEB) PCR, resulting in the removal of the triazole group linking the cDNA fragment to the 3' Illumina sequencing adapter. Following another Zymo DNA clean column purification, the samples were visualized on an agarose gel. cDNA libraries between 400-700bp were excised and purified using the Zymo Research Gel Recovery kit. Sequencing was performed by the UTMB sequencing core using an Illumina NextSeq 550.

Sequence assembly and analysis

Illumina ClickSeq sequencing analysis was performed by the Routh lab at UTMB.

QUALITY AND FILTRATION

Cutadapt was used to remove adaptor sequences. Following this, FASTX toolkit was used to remove the random hexamer sequences generated during cDNA synthesis, as well as sequences with a PHRED score below 20.

REFERENCE SEQUENCE

The analysis was performed using VEEV strain TC-83 GFP, complete genome.

VIRUS RECOMBINATION ANALYSIS

Bowtie was used to align the virus sequences to the reference genome, with up to one allowed mismatch. Those sequences that did not align using Bowtie were processed using ViReMa, a recombination mapper, to determine the incidence of recombination. These reads were normalized to the average number of reads aligning to the virus genome.

Infant mouse passaging and virulence

Six-day-old CD-1 mice (Charles Rivers, Wilmington, MA) were inoculated IC with 10^4 PFU of virus in a volume of 20 μ l. After 48 hours, brains were removed, weighed, and transferred to a tube with a steel bead. Media (DMEM supplemented with 10% FBS and gentamycin) was added to produce final concentration of 10% weight to volume. Brains were homogenized using a TissueLyser II (Qiagen) for 5 minutes at 26 beats/second, and then spun down for 5 minutes at 3.3 X g. Supernatant was transferred to a fresh tube and stored at -80°C. Plaque assays were used to determine virus titer. This information was used to dilute the virus for the next passage. 10 passages were performed in total.

Following passages 5 and 10, 6-day-old CD-1 mice were challenged SC with 10^5 PFU or PBS in a volume of 50 μ l. Animals were weighed daily for two weeks and monitored for survival.

Virus full genome Sanger sequencing

Virus RNA was extracted from the homogenized mouse brains using the QIAamp Viral RNA Minikit as per the manufacturer's protocol and stored at -80°C . Using 3 μ l of this RNA, the Superscript III RT PCR kit (Invitrogen) was used to generate cDNA by adding 5 μ l nuclease-free water, 1 μ l dNTPs (NEB), and 1 μ l random hexamers. This was incubated at 65°C for 5 minutes and placed on ice for 2 minutes. Following these incubations, 4 μ l MgCl_2 , 2 μ l 10X RT buffer, 2 μ l DTT, 1 μ l RNase OUT, and 1 μ l SSIII enzyme was added to the first tube and incubated for 10 minutes at room temperature, followed by 43°C for 90 minutes, and finally 50°C for 10 minutes. This was stored at -20°C .

High fidelity Phusion PCR (NEB) was used to generate approximately 1.5kb amplicons that tiled the entire TC-83 genome. In a PCR tube, 2.5 μ l of cDNA was added to 10 μ l 5X buffer, 1 μ l dNTPs, 1 μ l forward primer (20 μ M), 1 μ l reverse primer (20 μ M), 32 μ l nuclease-free water, 2 μ l MgCl_2 , and 0.5 μ l Phusion polymerase. The amplicon primers were as follows: 1V+1512C, 1210V+2874C, 2440V+4014C, 3725V+5263C, 4937V+6579C, 6207V+7800C, 7246V+9047C, 8443V+10281C, and 9883V+11422C. The PCR reactions were amplified using a 98°C hot start for 30 seconds, followed by 35 cycles of a 10 second 98°C denaturation, a 10 second 60°C anneal, and a 1.5 minute elongation at 72°C .

Following PCR amplification, amplicons were visualized by running the entire contents of the reaction on a 1% agarose gel in TAE buffer. The bands were excised and purified using the QIAquick Gel Extraction kit as per the manufacturer's protocol. DNA was eluted into 35 μ l of nuclease-free water and stored at -20°C .

Sequencing reactions were prepared by adding 1 μ L of a 2 μ M primer (Table 4.1) to 5 μ L DNA, 2 μ L 5X sequencing buffer, and 2 μ L BigDye (Applied Biosystems). The sequencing reactions were amplified using a 96°C hot start for 2 minutes, followed by 30 cycles of a 10 second 96°C denaturation, a 5 second 50°C anneal, and a 4 minute elongation at 60°C. Following this, sequencing reactions were purified using Performa spin columns (EdgeBio) as per the manufacturer's protocol, and loaded onto the Applied Biosystems 3500 Genetic Analyzer sequencer. Sequences were analyzed using Sequencher version 5.0.1.

Statistics

GraphPad Prism was used to perform all statistical tests, which are described in the text.

RESULTS

Phenotypic variation in EP stock

Work in previous chapters suggested that differences in virus EP stock led to differences in phenotypes, both *in vivo* (Chapter 2) and *in vitro* (Chapter 3). To further examine this, EP stocks of TC-83 and TC-83 3x were generated independently in triplicate (Illustration 4.1). The TC-83 3x that was used for this experiment only contained the three low-fidelity RdRp mutations. After each clone was linearized, purified, and transcribed, virus RNA was electroporated into BHK cells and collected at 32 and 56 HPE.

At 32 HPE (Figure 4.1 A&B) and 56 HPE (not shown), no significant differences in CPE were observed between the two viruses or EP replicates. The titers from 56 HPE was slightly higher for all virus stocks, so these were selected for further characterization. There was no significant difference in virus titer as measured by plaque assay (Figure

4.1C) or RT-qPCR (Figure 4.1D), and thus no significant difference in specific infectivity (i.e. the ratio of infectious virus to virus RNA copy number).

In the prior studies described in chapter 3, TC-83 3x was attenuated in mosquito cells at a low MOI when using two different EP stocks, but this attenuation was lost when using a third stock. However, the control TC-83 was always infectious when using this MOI. To determine if there were differences in mosquito cell attenuation for these new EP stocks, mosquito cells were infected using an MOI of 0.01 using 10 replicates, and supernatant collected at 24HPI was tested for infectious virus using a CPE assay. In stark contrast to the results described in chapter 3, all EP stocks generated for this experiment were attenuated, regardless of fidelity (Figure 4.1E). Additionally, there was no significant difference in the percentage of replicates negative for infectious virus.

Illumina sequencing for virus variants during EP stock generation

To determine the changes in virus diversity and minority variants that occurred when preparing clone-derived TC-83 and TC-83 3x, Illumina NGS was used to sequence each step of the EP procedure (Illustration 4.1). Equal amounts of linearized and purified virus clone DNA were used for each *in vitro* transcription, with 5 μ L of the transcription product used for EP, as per standard protocol. There was no significant difference in virus diversity for TC-83 and TC-83 3x during any EP step. However, TC-83 3x trended towards producing higher EP stock diversity, with p-values approaching the 0.05 significance cut-off (Figures 4.2 A&C). Strikingly, however, the amount of virus diversity produced by the EP replicates varied enough to cause overlap in the diversity observed for individual TC-83 and TC-83 3x replicates.

Overall diversity at one EP procedure step did not correlate with diversity at a later step (Figures 4.2 B&D). In contrast to this, the number of high frequency minority variants grew during each sequencing step (Figures 4.2 E&F). There was no difference in the number of high frequency minority variants between TC-83 and TC-83 3x until the

EP step, where TC-83 3x generated significantly more variants (Mann-Whitney U, $p < 0.01$) (Figure 4.2E). Additionally, while high conservation in the location and amplitude of mutation hotspots for the DNA and *in vitro* transcription stocks was observed in Figures 4.3-4.4, there was clearly more variation in the EP stocks, especially for TC-83 3x.

Interestingly, while 13-66% of high frequency DNA minority variants were later found in the *in vitro* transcription stocks, 80-93% of high frequency *in vitro* transcription minority variants were also found in the EP virus stock (Tables 4.2-4.3). These variants were almost entirely conserved between each EP stock, regardless of RdRp fidelity. However, these conserved mutations only comprised 67% of the high frequency TC-83 3x EP mutations and 76% of those identified for TC-83. Of the remaining mutations, the majority were unique to each stock, with only 22% of TC-83 and 10% of TC-83 3x high frequency mutations found in another EP stock. Additionally, some variants were only found in high amounts in one step, but not another. For example, A7653C was found at a high frequency in all DNA stocks, but was not found in high amounts during transcription and EP. Additionally, T2507+T or T2507A was found in all transcription stocks at high levels, but not during EP.

Illumina sequencing of EP stocks to determine mechanisms of *in vitro* mosquito attenuation

As all of the EP stocks generated during this chapter were attenuated in mosquito cells when using a low MOI (Figure 4.1E), these stocks were compared to the TC-83 and TC-83 3x EP stocks that were not attenuated in Chapter 3. There was no significant difference in overall virus diversity between attenuated and unattenuated EP stocks (Figure 4.5 A-B) or in the number of high frequency mutations (Figure 4.5 C). Of these diversity hotspots, 62% of the variants were shared between attenuated and unattenuated virus stocks (data not shown). The remainder of these variants was diverse, with no high

frequency variants specific to either *in vitro* phenotype. Additionally, while some small differences were observed in the mutation frequencies of the attenuated versus unattenuated stocks, none were severe enough to explain the phenotypic changes (Figure 4.5 D-E). Thus, no clear differences in virus diversity or the variants required for a successful infection of mosquito cells at a low MOI were found.

Rapid loss of GFP fluorescence during low-fidelity TC-83 passaging

To examine reporter gene stability, three independent replicates of TC-83 and low-fidelity TC-83 3x GFP were passaged 10 times on Vero cells using an approximate MOI of 0.5. Over the course of this passaging, reduced GFP expression for low-fidelity TC-83 3x was observed beginning at passage 4 (Figure 4.6B). In contrast, GFP loss was not observed for the TC-83 replicates until passage 8 (Figure 4.6A).

To quantify this loss, the number of fluorescent plaques was compared to the number of plaques for passages 5-10 (Figure 4.7). Until passage 10, almost every TC-83 plaque was fluorescent, and the largest PFU:GFP difference was approximately 1:30, which was only observed for one replicate during the final passage. On the other hand, all low-fidelity TC-83 replicates experienced an approximately 500-1500-fold decrease in fluorescence by passage 10, orders of magnitude higher than the ratios observed for the TC-83 GFP passaging replicates. As a low-fidelity SINV mutant was found to produce DI particles at high rates (64, 372), we hypothesized that low-fidelity TC-83 was also recombining at higher rates than TC-83, resulting in rapid GFP gene removal.

Low-fidelity TC-83 GFP gene removal is enhanced

ClickSeq was used to generate Illumina sequencing libraries, allowing the frequency of virus deletion mutants to be quantified. All three TC-83 GFP replicates contained minority deletion variants that were able to selectively remove the GFP reporter gene by passage 10 (Figure 4.8). Deletion inside the GFP gene was higher than

for any other gene, even as soon as passage 1. In support of our hypothesis, low-fidelity TC-83 GFP was much more efficient at removing the GFP gene, as the frequency of deletions within GFP gene were far higher than those of TC-83 GFP (Figure 4.9).

The first replicate of each virus was chosen for further analysis, as these both had median levels of decreased GFP fluorescence in Figure 4.7. Interestingly, for both viruses, peak recombination appeared in the middle of the GFP gene, and slowly spread out over the course of passaging to the entire gene (Figure 4.10). TC-83 3x was efficiently removing the entire GFP fragment by passage 3, while TC-83 needed until passage 8 to reach similar levels of GFP removal. This clearly demonstrated that TC-83 3x is much more efficient at recombination than TC-83.

Genetic stability *in vivo*

The low-fidelity TC-83 3x mutant and TC-83 were subjected to 10 serial intracranial passages in infant mice to determine if compensatory mutations accumulated *in vivo* (Appendix 2, stocks 1-2). To assess changes in virulence during passaging, passage 5 and 10 virus was injected subcutaneously into 6-day-old mice. TC-83 and TC-83 3x both gained virulence by passage 5 compared to their unpassaged counterparts in Figure 2.2 (Kaplan-Meier test, $p \leq 0.0001$) (Figure 4.11A). Figure 2.2 was chosen for statistical comparison, as the same stocks were used for both of these experiments. At passage 5, the 3x mutant reached virulence equivalent to that of the original, unpassaged TC-83 with no significant difference in time to death. Interestingly, no significant changes in virulence occurred between passage 5 and 10 for either virus. This indicates that TC-83 3x can only reach virulence equivalent to unpassaged TC-83 and is unable to increase in virulence past that point.

Illumina sequencing for virus variants following *in vivo* passaging

Illumina sequencing following mouse brain passage 5 showed an increase in diversity for the low-fidelity mutant relative to previous *in vitro* results (Figure 4.11B). Curiously, while diversity hotspots increased for TC-83 3x, the 6k hotspot observed after cell culture passage in Chapter 2 (Figures 2.3, 2.5 & 2.7) was greatly reduced for both passage 5 viruses (Figure 4.11 D&E). Although a different EP stock was used for infant mice passaging than the stock used to determine virus diversity during Chapter 2 (Figures 2.3-7), TC-83 3x still exhibited fewer U-C mutations (Figure 2.4), suggesting that this may be a stable phenotype for low-fidelity TC-83.

While TC-83 3x was more diverse than the parent TC-83 as measured by Illumina virus sequencing, fewer revertents occurred at the E2 mutation required for TC-83 attenuation (Figure 4.11C) (307). Due to the position of the 5'UTR attenuation mutation, coverage was too low to assess true differences in the potential for this site to also revert, but no reads contained the revertent mutation for either virus. Following passage 10 in mouse brains, Sanger sequencing was used to identify several SNPs (Table 4.4). TC-83 and TC-83 3x each produced 2 SNPs following 10 infant mouse passages. None of these SNPs reverted the TC-83 mutations that cause attenuation or the inserted RdRp mutations. Additionally, no convergent mutations were found in all passage series.

DISCUSSION

To ascertain the genetic and phenotype stability of our low-fidelity variant, we subjected TC-83 and TC-83 3x to various tests designed to examine stability when the viruses are first generated, as well as after multiple *in vitro* and *in vivo* growth cycles. Contrary to our initial hypothesis, the genetic stability of TC-83 3x is quite stable, with no evidence of reversion in any of our genetic stability assays. However, some variation was discovered.

Errors are generated during each step of the Illumina NGS procedure and form up to 1% of detected variants (377). To correct for these errors, numerous biological controls

(e.g. CirSeq (378), DNA clone controls (379), primer IDs (380)) as well as *in silico* programs (e.g. DeepSNV (379), ShoRAH (381), PredictHaplo (382), etc.) have been developed. These methods are not perfect. For example, while some biological controls account for PCR errors, these also fail to control for errors generated during the error-prone RT-step (i.e. infectious DNA clone controls (379), primer IDs (380)). Unfortunately, protocols that are able to control for RT errors also require high amounts of input RNA, making widespread use of these techniques unrealistic (378). Additionally, even when coverage is high and mapping is accurate, *in silico* approaches can either be too conservative, causing true variants to be missed, or too lax, resulting in a lack of precision (377). Variant callers can balance these two extremes by using various statistical models to predict expected variant error. However, unknown biases commonly result in greater than expected fluctuations in variants.

The EP sequencing data summarized in Tables 4.2-4.3 suggest that our rare virus variant pipeline is liberal when identifying these variants, which due to the difficulty of calling rare virus variants accurately is not surprising. For example, all of the high frequency DNA variants were biased towards either the negative or positive sense strands, which is indicative of sequencing artifacts (379). This was true even when only reads with a quality score of 30 or above were used (data not shown). Interestingly, some of these sequencing artifacts, such as T9988A-G, were also found in high proportions in the transcription and EP stock, suggesting that there was high Illumina sequencing bias for these variants or that, indeed, these are true variants. While there was a link in the variants identified during all three EP stock steps, the variants in the transcription step were positively correlated with those that appeared in the EP. These may also be sequencing artifacts. However, as *in vitro* transcription is known to be error-prone, generating approximately the same error as an RdRp (101), and because these variants were much less common in the plasmid stock, this suggests that the errors that occur during *in vitro* transcription are largely carried over into the EP virus stock population.

Intriguingly, the errors generated during *in vitro* transcription largely form the common high frequency variants found in the different EP stocks. As this experiment only examined T7 promoted clone sequences, it would be interesting to use different RNA polymerases during *in vitro* transcription to examine how this might alter the variants that occur during EP, as well as the effects this may have on virus fitness.

Continuing the trend of inconsistency, all EP stocks generated during this subaim were sensitive to low MOI mosquito cell infection, regardless of RdRp fidelity. These attenuated stocks were compared to previously generated stocks that grew well in mosquito cells at a low MOI. However, no differences were identified. This suggests that factors beyond those measured here are responsible for the mosquito cell phenotype instability observed here and in chapter 3. Importantly, however, each EP stock exhibited slightly different amounts of overall diversity and was composed of a unique repertoire of high frequency virus variants, especially for low-fidelity TC-83, showing that EP stocks are not the same. In the future, it would be interesting to test these different EP stocks for variation in growth kinetics and/or *in vivo* (i.e. infant mice LD₅₀) to determine differences in virulence, as it is not well understood how specific minority variants may contribute to different phenotypes.

Previous research using a low-fidelity variant of SINV found that it also produced an overabundance of DI particles relative to the original virus when passaged using a high MOI (64). To determine if this was also true for our fidelity mutant, we passaged TC-83 GFP and TC-83 3x GFP ten times in Vero cells. However, a low MOI was used for a more accurate representation of virus recombination. Until recently, it was not feasible to observe recombination variants that naturally occur in virus populations due to the high amounts of recombination artifacts generated by typical Illumina sequencing library procedures (65). However, due to the ClickSeq method of generating libraries (65), it has now become possible to observe the regions in the virus genome most prone to recombination. It is important to understand where virus recombination occurs, not

only to understand the role of recombination in virus evolution, but also to comprehend how RNA viruses remove inserted genes, such as reporter genes used to visualize or quantify virus infection (i.e. GFP, luciferase). Reporter gene instability is a common phenomenon for RNA viruses, resulting in rapid loss of the reporter gene both *in vitro* (383-387) and *in vivo* (383, 385, 386). Understanding the frequency of reporter gene removal, as well as where removal is most likely to occur, at the level of the entire virus population will aid in the design of reporter genes with increased stability.

We found conserved regions of recombination in the genome, as well as a slow, but persistent removal of GFP that was highly specific to only the inserted gene. Additionally, low-fidelity TC-83 3x was much more efficient at removing the extraneous GFP gene, suggesting recombination and fidelity for low-fidelity alphavirus RdRp mutants may be closely entwined (64). This also implies that experiments requiring reporter genes may not be very stable when using these low-fidelity constructs. Future experiments need to examine recombination differences in an unaltered genome to better understand the subtle changes in recombination that naturally occur.

Finally, to ensure that our observations from the *in vitro* data were consistent with virus behavior *in vivo*, TC-83 and TC-83 3x were passaged IC in infant mice. Perhaps counterintuitively, the 3x hyper mutator variant, while undergoing an initial increase in virulence during *in vivo* passaging, only reverted to the same level of virulence as unpassaged TC-83. This is likely due to an increased amount of unfit virions (e.g. defective interfering particles), which hamper wt virus virulence, as well as the inability of the 3x mutant to revert the inserted RdRp mutations. Also, the passage 10 results for each virus were very similar to the passage 5 data, which demonstrates that the low-fidelity mutant exhibits decreased risk of reversion to wt virulence compared to the original TC-83. While promising, this experiments bears repeating in the future to ensure that these results are consistently observed.

Overall, we have shown our TC-83 3x mutant to be genetically stable, with no reversion of the RdRp or TC-83 attenuating mutation, although not always phenotypically stable. Importantly, TC-83 3x was much less prone to reversion *in vivo*, which has always been problematic for TC-83 (292, 295), suggesting that our low-fidelity mutant is still an improvement over the original vaccine.

Table 4.1: Sequencing primers.

Primers used during the PCR amplification and sequencing of virus isolated TC-83 or TC-83 3x infected infant mice brain. “V” designates primer sequences complementary to the virus sequence (i.e. positive-sense), while “C” designates primer sequences that bind to the minus-sense strand.

Illustration 4.1. EP stock variability experiment.

To test differences in EP stocks, three independent EP replicates were each generated for TC-83 and TC-83 3x. First, 5µg of TC-83 or TC-83 3x was linearized using the restriction enzyme MluI. After purification, 250ng of this DNA was used to generate RNA copies of the virus genome. 5µL of this RNA was then electroporated into BHK cells to generate infectious virus. The linearized DNA, in vitro transcribed RNA, and EP stock RNA were sequenced using an Illumina NextSeq 550 to test for differences in diversity and minority variants. To test for differences in EP stock phenotypes, C7/10 mosquito cells were infected at an MOI of 0.01 using 10 replicates of each EP stock. Following a 24-hour incubation, the supernatant of the infected C7/10 cells was collected, clarified, and used to infect Vero cells. If Vero cell CPE was observed for all 10 replicates of an EP stock, the stock was considered to be unattenuated. However, if any of the 10 replicates failed to produce CPE in Vero cells, the EP stock was considered to be attenuated. In this illustration, blue represents replicate 1, red represents replicate 2, and black represents replicate 3.

Figure 4.1: Variation in EP stock phenotype.

BHK cells were EP in triplicate with TC-83 or TC-83 3x. At 32 HPE there was no difference in the CPE produced by TC-83 (A) or TC-83 3x (B). Using an unpaired t-test, no significant difference in virus titers as measured using plaque assay (C) or RNA copy number using RT-qPCR (D). Mosquito cells were infected with an MOI of 0.01 using TC-83 or TC-83 3x from the electroporation stocks (E). No significant difference in low MOI mosquito cell infectivity was observed using an unpaired t-test.

WHAT IS A FIDELITY MUTANT?

Chapter 5. Discussion

In this dissertation, a low-fidelity TC-83 was found to improve upon the unaltered TC-83 in a variety of ways. For example, this mutant enhanced the neutralizing antibody response when used as a vaccine, decreased virulence in an infant mouse model, decreased replication *in vitro* in mosquito cells, was genetically stable, and was unable to increase in virulence on par with TC-83 when passaged in infant mice. However, when some of these assays were repeated, such as the infant mouse virulence experiments and low MOI mosquito cell infections, phenotypes were not reproduced, likely due to differences in EP stocks. While frustrating, this is a common problem in science, referred to as the replication crisis (388). This is especially concerning for the vaccine candidate described in this dissertation, as these inconsistent outcomes represent a significant barrier against the development of fidelity mutants as live-attenuated vaccine. These inconsistencies necessitate further consideration of the putative characteristics of a virus fidelity mutant.

DEFINING A FIDELITY MUTANT

The most basic definition of a RNA virus fidelity mutant is a virus that produces more or less error when replicating relative to unaltered virus. While identifying a fidelity mutant may appear straightforward, it can be difficult to link certain mutations to changes in fidelity. Additionally, questions arise that are difficult to answer. For example, is a virus a fidelity mutant if it is not high or low-fidelity for all mutation types? For half of the mutation types? As long as the overall balance is consistently higher or lower than the control virus? While this may be less of a concern for fidelity mutants that are resistant to

multiple types of nucleoside analogs, this is important to know for fidelity mutants that only display resistance to one type (78).

As the low-fidelity TC-83 discussed during this dissertation displays inconsistent changes in the frequency of certain mutations, these questions must be asked. The answer likely depends on the purpose of the project. For example, if the goal is to cause further attenuation of a vaccine, this is not likely to be important as long as the attenuation is stable. However, this knowledge is important if a vaccine phenotype is not stable or when asking basic science questions. Unfortunately, the frequency of different mutations is not available for most fidelity mutants, and the majority of those mutants for which this is available either find an imbalance in different types of mutation (74, 79, 83) or do not provide enough information to determine this (63, 88).

ARE SOME FIDELITY MUTANTS ACTUALLY KINETIC MUTANTS?

Theoretically, fidelity mutants should not be attenuated *in vitro*, because changes in fidelity should not be detrimental to virus replication (353). The lack of a growth defect is a desirable characteristic for a LAV, as this is one less barrier against production of the vaccine. This is especially true for a vaccine such as TC-83, which grows to very high titers. However, many fidelity mutants do grow slightly slower than wt virus (72, 76, 82, 85, 389), especially in primary vertebrate cells (67, 77) and mosquito cells (82-84). While the mechanisms behind this slight attenuation are not well understood, this suggests that in a more complex environment, such as those found *in vivo*, that fidelity mutants may essentially behave as kinetics mutants (67). As fidelity mutants commonly display lower titers and tissue restriction *in vivo* (46, 68, 69, 73, 80, 82, 86, 339), perhaps the lower titers produced by fidelity mutants act as a bottlenecks, producing a virus population without the correct mutant spectrum to infect the same number of tissues as wt virus. Additionally, a drop in the virus titer due to slightly lower replication kinetics likely makes the infection easier for the host to control, which could be a confounding

factor in the attenuation commonly observed for fidelity mutants. This begs the question of whether fidelity and kinetics can ever truly be separated.

Newer technologies may aid in determining the differences between fidelity and replication, if they do indeed exist. For example, measuring the incorporation of 1-2 nt, as is common in sym/sub replication kinetics experiments, is not an accurate depiction of virus replication, which requires the RdRp to replicate not one, but thousands of nts. A new technique, known as magnetic tweezers, addresses this by attaching a coverslip to one strand of an approximately 3kb dsRNA molecule and a magnetic bead to the other (390, 391). As the RdRp replicates the RNA, this releases the beaded RNA strand from the anchored RNA strand, allowing the magnetic bead to migrate upwards towards a magnet. The longer the distance between the coverslip and the magnet, the more efficient the RdRp is at replication. Sym/sub replication studies have shown low-fidelity viruses to be fast, but inaccurate nt incorporators (18, 46, 77, 83). However, magnetic tweezers have shown that low-fidelity PV H273R also displays an increased number of pause events, which are associated with the incorporation of incorrect nts (390). This suggests that low-fidelity polymerases are prone to stuttering when replicating, which may have impacts on other polymerase-associated events, such as recombination. Understanding the role of processivity and its ties to fidelity is one step towards closing the gap of knowledge between what is observed during very simple measures of virus replication, such as sym/sub replication, and what is observed in cell culture and animals.

For some viruses, such as those in the alphavirus genus, the RdRp is unstable, and thus fine measurements of RdRp replication kinetics are not possible. Single-cell sequencing presents an exciting alternative, while also offering a better understanding of the fate of each virus-infected cell (392-394). Interestingly, when low-fidelity H273R PV was examined using this technique, it was found to cause a reduced number of infections compared to wt virus, as well as delayed replication initiation (392). However, H273R was able to replicate quickly enough to reach peak titer at the same time as wt PV. This

experiment confirmed what had been measured using the sym/sub system (79), suggesting that some of the measurements that once required cell-free systems to assay can now be performed in cells. This also improves upon the more standard biochemical and growth curve kinetics assays by allowing for the measurement of thousands of infections at the same time in replicate, instead of only examining a composite. However, as these techniques are relatively new, this type of analysis is not yet widely available.

FIDELITY MUTANT STABILITY

As John Allen Paulos once said, “uncertainty is the only certainty there is,” (395) which seems to be especially true of RNA virus fidelity mutants. While fidelity mutants exhibit certain trends, like attenuation in one environment versus another, these do not appear to always be stable. During studies described in chapters 2-4 of this dissertation, there were multiple *in vivo* and *in vitro* examples of inconsistent TC-83 phenotypes with no clear explanation as to the reason for this instability. This is not entirely surprising, as RNA virus fitness landscapes are hypothesized to be turbulent (20, 22), and there is a paucity of methods to aid in the prediction of these landscapes. When examining the literature, most fidelity mutants have only been characterized in the paper showcasing their discovery, and those that have appeared in more than one publication are used to examine something novel. Occasionally, however, assays are repeated, and these commonly show inconsistent fidelity and/or phenotypes, as described below.

The high-fidelity HEV71 mutants were first described by Sadeghipour et al. in a pair of concurrent papers (72, 339). While G64R, G64T, and S264L RdRp mutations were all able to increase HEV71 fidelity *in vitro* (72), only S264L caused attenuation *in vivo* when using 5-day-old BALB/c mice, which have an intact IFN response (339). However, when these mutants were later examined in a slightly different virus backbone that was not murine-adapted, G64R was approximately 3-fold less virulent than S264L when using 10-day-old AG129 mice (IFN-receptor deficient), which itself was 37-fold

less virulent than the control virus (73). This is odd, because these results suggest that small changes to the HEV71 backbone can cause dramatic changes in virulence. However, if the highly conserved PV G64 residue is able to increase fidelity in a distantly related enterovirus such as HEV71, this is not likely to be the cause of differences in virulence. Alternatively, changing the mouse model may have resulted in decreased G64R virulence in AG129 mice. However, as PV G64S (67, 68) and other fidelity mutants (46, 71, 75-80, 82, 86, 87) are attenuated in mice with intact IFN, it would therefore be predicted that the HEV71 G64R mutant would also be attenuated in the BALB/c model. Thus, there is no clear explanation for why the HEV71 G64R mutant would behave so differently in the hands of different labs.

The most famous and highly studied fidelity mutant, high-fidelity PV G64S, is not immune to incongruent results. The first study to examine PV G64S *in vivo* infected cohorts of 10-week-old PVR mice IM with 5×10^6 PFU of G64S or wt PV (67). Of the 25 mice per cohort, approximately 10 G64S PV mice exhibited no symptoms over the course of infection, while only 5 of the mice infected with wt PV exhibited no symptoms. While it was stated that fewer deaths were recorded for G64S infected mice, this data was not shown. In contrast to this, Vignuzzi et al. (68) found that 100% of 8-week-old PVR mice infected IM with 10^7 PFU of G64S were able to survive infection, suggesting that this G64S was more attenuated than it was in the initial *in vivo* virulence study (67). Vignuzzi et al. also used this experiment to calculate LD₅₀ values, which were 1.2×10^6 PFU for wt PV and 3.9×10^8 PFU for G64S, a 325-fold difference. These are the exact same LD₅₀ values published in a later paper also by the Vignuzzi lab (69). This alone would not be too concerning as both papers demonstrated that G64S PV was more attenuated *in vivo* than wt PV. However, a recent dissertation (396) reported complete hind limb paralysis in all mice (which mice cannot recover from) when 4-6-week-old PVR mice were infected IM with 10^7 PFU of G64S, as well as no difference in the LD₅₀ values for G64S versus wt PV. Intriguingly, for this group, G64S was only more attenuated than wt PV

when 5-week-old mice were infected IP. This report was further reinforced by the most recent paper to examine G64S virulence, which also found 5-week-old PVR mice infected IM with 10^7 PFU of this mutant or wt PV to succumb to infection at identical rates (63). There was also no difference in the LD₅₀ values. Xiao et al. suggested that this difference may be due to age, as the wt PV LD₅₀ for 8-week old mice in this study was 10^7 PFU versus 5×10^5 PFU for 5-week-old mice. However, it is unknown how this translates to high-fidelity G64S PV, and does not explain why the LD₅₀ values would be so similar for wt PV and G64S. Again, as seen for HEV71, fairly large differences in phenotypes were observed when different labs examined this fidelity mutant.

The inconsistency observed for *in vivo* attenuation with HEV71, PV, and our TC-83 mutant suggest that this is a prevalent occurrence for fidelity mutants. This is concerning, as one of the best pieces of evidence for the theory of virus quasispecies is the original high-fidelity PV study by Vignuzzi et al., which demonstrated that it was the overall diversity of the quasispecies that caused virulence, not any one mutation (see “Poliovirus” in the introduction). Perhaps it is not surprising that *in vivo* attenuation is inconsistent, as it is hypothesized that high fidelity viruses will be less likely, not entirely unable, to produce the mutants necessary for different tasks (e.g. IFN evasion, host switching). This is supported by recent studies that have correlated specific minority variant mutations to increases in virus fitness (204, 397). Additionally, while low-fidelity viruses are hypothesized to overproduce deleterious, interfering mutants, perhaps some stocks harbor more interfering mutants than others, while others may generate high fitness mutations due to random chance, leading to differences in attenuation.

While the mechanism(s) behind this variation in attenuation *in vivo* have yet to be determined, a study by Xiao et al. hints that PV is able to overcome increased fidelity by using recombination, suggesting that recombination may be playing a compensating role for other fidelity mutants (91). Additionally, as suggested by Xiao et al., the age of the mouse could explain the severe changes in attenuation, although this may be specific to

PV G64S. If so, this is of large concern for vaccine development, as this suggests that, at best, only certain human populations would benefit from the increased vaccine attenuation, or at worst, that there would be no discernable difference between vaccines with or without altered fidelity. This needs to be examined closely to determine exactly what is causing these changes in virulence and if these mechanisms are conserved between different fidelity mutants. At minimum, this suggests that separate LD₅₀s should be performed for each altered fidelity mutant stock to ensure consistent attenuation.

Additionally, the diversity of fidelity mutants can be somewhat inconsistent. For example, the mutation frequency of high-fidelity CHIKV C483Y was initially determined to be approximately 1.4-fold higher than wt virus (80). Five independent EP stocks for each virus were used to determine these mutation frequencies, and, interestingly, there was large overlap of the mutation frequency error bars between the two viruses, similar to our EP results in Chapter 4. Later publications that used C483Y as a control found no difference in the mutation frequencies generated by C483Y or wt CHIKV (81, 82), which may explain why the TC-83 C488Y mutant examined in Chapter 2 had no effect on virus fidelity. Interestingly, the mutation frequency per 10⁴ nt was slightly higher for wt CHIKV in the initial study compared to more recent papers (5.1 versus 4.4 and 4.4), as well as slightly lower for C483Y (3.6 versus 4.1 and 4.2), suggesting that slight fluctuations in both the wt and RdRp mutant stock can reduce or entirely ablate significant differences in replication fidelity. Alternatively, this change in the CHIKV C483Y mutation frequency is perhaps explained by an nsP2 mutation, G641D, which was found during the initial high-fidelity CHIKV identification (80) and later shown to also increase CHIKV fidelity (81). It would be interesting to determine the occurrence of this nsP2 mutation in different CHIKV C483Y EP stocks, and whether the appearance of this mutation in the minority variant population is correlated with decreased mutation frequencies. Importantly, while the flux in this CHIKV mutant's replication fidelity is likely one of the more egregious examples, some degree of mutation frequency flexibility

is probably to be expected due to differences in mutation frequency measurements, random chance, and other unknown variables (Figure 5.1).

Unfortunately, for many fidelity mutants we may never know what aspects are or are not repeatable, as the majority of fidelity mutants have not been closely and repeatedly examined. This is problematic, as outcomes from experiments using putative fidelity mutants are being used to draw significant conclusions regarding RNA virus evolution (37, 372). Without a thorough understanding of the shortcoming of each proposed fidelity mutant, however, their use is likely to lead to ambiguous and misrepresentative results. Thus, it is now important for the fidelity mutant field to take a step backwards to truly assess what it means for a virus to display altered fidelity.

USING FIDELITY MUTANTS AS VACCINES

As described above, the inconsistent attenuation observed with fidelity mutant viruses suggests that fidelity mutants are not yet ready for mainstream use as vaccine candidates. If the outcome of virus recovery is variable and leads to major shifts in the observed phenotype for a fidelity mutant, despite the same consensus level mutations being present, this creates a significant barrier for developing a controlled manufacturing process. At minimum, correlates of attenuation need to be developed by generating many pools of virus stock, establishing a correlate of protection (e.g. a significantly lower LD₅₀ in a mouse model), and sequencing these stocks to determine minority sequences associated with attenuation or virulence. It would also be important to passage these stocks to guarantee stability of the vaccine genotype and phenotype and reduce adverse events following vaccination.

Perhaps our low-fidelity TC-83 vaccine candidate could be further improved upon by further attenuation beyond the E2 and 5'UTR mutations responsible for its initial attenuation. For example, inserting our low-fidelity mutations into a closely related VEEV vaccine candidate (e.g. V3526 (311)) could result in a more consistently

attenuated vaccine candidate. It may also be interesting to explore differences in vaccine attenuation caused by different methods of preparing virus stocks. As shown in chapter 4, minority variants created during *in vitro* transcription are largely retained in the EP stock. Different plasmid promoters (e.g. T7, SP6, CMV) and the repercussions of these on virus stock genotypes and phenotypes should be explored in future work. Using a CMV promoter would be especially interesting, because this would allow for the delivery of the vaccine candidate as a plasmid via a gene gun, as described in the overall introduction. This method of vaccine delivery would eliminate the errors generated during the *in vitro* transcription step necessitated by our EP virus stocks and would streamline the manufacturing process.

While using fidelity mutants as vaccines held such large promise during the initial high fidelity poliovirus studies, the work described in this dissertation and elsewhere suggests that this method of virus attenuation is only workable if attenuated viruses are used as the backbones for these mutants. There is some historical evidence for this, as the vaccine for yellow fever, 17D, is believed to be a safe and effective vaccine based upon multiple attenuation mutations as well as a high fidelity polymerase. Perhaps in the future the instability exhibited by our low-fidelity vaccine candidate, as well as other fidelity mutants, will be overcome, allowing for these fidelity mutants to be used as vaccines. Until then, however, fidelity mutants will remain as a tool for basic science, at least when used in a well-controlled setting.

Figure 5.1: Variation in fidelity mutant mutation frequencies.

Variation in the mutation frequency of unaltered virus versus: high-fidelity PV G64S (68, 69, 79), high-fidelity CHIKV C483Y (80-82), or low-fidelity CHIKV C483G (81, 82). Dashed lines indicate equal levels of mutation frequency for control and fidelity mutant viruses.

APPENDIX 1. VEEV TRANSMISSION CYCLE *IN VITRO*

No work has examined genetic/phenotypic stability of arbovirus fidelity mutants in a transmission cycle. To better understand how TC-83 and the low-fidelity mutant adapt when confronted with alternating animal and vector environments, these viruses were serially passaged in duplicate using mosquito cells, vertebrate cells, or cycling between the two. Also, to determine if any adaptive changes occurred while virus was passaged in cells with functional cellular immunity, interferon competent (MRC-5) or incompetent (Vero) vertebrate cells were used alongside siRNA competent (U4.4) or incompetent (C7/10) mosquito cells (Illustration 6.1).

METHODS

Cell culture

Vero (African green monkey kidney), HEK-293 (human embryonic kidney), MRC-5 (human fetal lung fibroblast), and Baby Hamster Kidney (BHK) cells were obtained from the American Type Culture Collection (ATCC) (Bethesda, MD) and maintained in DMEM (Gibco) supplemented with 10% Fetal Bovine serum (FBS, Atlanta Biologicals), and 500µg/mL gentamycin (Corning) in a 37°C 5% CO₂ incubator. C7/10 cells were maintained in DMEM supplemented with 10% Fetal Bovine serum, 1% Minimal Essential Medium Nonessential Amino Acids (Gibco), 1% Trypose Phosphate Broth (Sigma), and 500µg/mL gentamycin in a 30°C 5% CO₂ incubator. U4.4 cells were maintained in Mitsuhashi and Maramorosch media (Sigma) supplemented with 20% FBS, 2% Sodium Bicarbonate (7.5%) (Gibco), and 500µg/mL gentamycin in a 30°C 5% CO₂ incubator.

Plaque assay

One day prior to infection, 6-well or 12-well Vero plates were plated using 250,000 or 500,000 cells per well respectively to ensure approximately 90% confluency the following day. Virus stocks were diluted 1:10 8 times using 225µL DMEM (supplemented with 2% FBS and gentamycin) and 25µL virus. This dilution series was either performed using 1.5mL tubes (using vortexing to mix) or 96 well plates (using pipetting to mix). Media was then decanted from a cell culture plate and 100µL (12-well plate) or 200µL (6-well plate) of each dilution was added to a well. This was performed in duplicate. The infected monolayers were stored in a 37°C 5% CO₂ incubator for 1 hour and were gently shaken every 15 minutes to ensure an even infection distribution. After this incubation, a 0.4% agarose overlay (1 part 2% agarose (Lonza) in filter-purified water to 4 parts DMEM supplemented with 2%FBS and gentamycin) was added to each well, and the plates were returned to the incubator. Following a 48 hour incubation, the monolayers were fixed for 30 minutes using 10% formaldehyde (Fisherbrand) before the agarose plugs were removed and the monolayer was stained with 0.25% crystal violet solution (Fisherbrand). The plates were then washed with water and allowed to dry before plaques were counted.

PFU per mL was calculated using the following formula: $\text{PFU/mL} = (\text{dilution} \times \text{number of plaques}) (1000/\text{amount plated})$, with “dilution” equalling the dilution at which the plaques were counted and “amount plated” equalling the amount of virus added when infecting the cells (i.e. 100µL for 12-well plates and 200µL for 6-well plates).

TC-83 passaging

One day prior to infection, 6-well plates were seeded with 500,000 Vero or MRC-5 vertebrate cells or 1,000,000 U4.4 or C7/10 mosquito cells. The day of the infection, one well of cells for each cell type was counted using a hemocytometer and used to determine the virus dilutions necessary for an MOI of 0.1. Once diluted, media was decanted from the 6-well Vero cell plate and 200µL was used to infect each well. These

infections were performed using two replicates per virus. Following the infection, the plate was transferred to a 37°C (vertebrate cells) or 30°C (mosquito cells) 5% CO₂ incubator for 1 hour with occasional shaking. When the incubation was complete, the inoculum was removed and 2mL of DMEM supplemented with 2% FBS and gentamycin (vertebrate cells) or the standard mosquito cell media was added to each well. The plates were then returned to the appropriate 5% CO₂ incubator for 24 hours.

After the 48 hour incubation, the virus was transferred to a tube with FBS to a final concentration of 20% FBS. This was centrifuged for 5 minutes at 0.8 X g and transferred to a new tube. These tubes were stored at -80°C. Plaque assays using Vero cells were used to determine virus titer. Six total passages were performed.

To determine changes in plaque size over the course of passaging, plaque assays were performed as per the usual protocol. All TC-83 plates were done in one batch, while all the TC-83 3x plates were done in another batch to insure that differences in cell confluency would not act as a confounding variable for differences in plaque size. After 48 hours, the cells were fixed and stained following the usual plaque assay protocol, and a picture was taken using an iPhone 6 (Apple) of each plate. The plaque size of 10 plaques per virus group was measured using the Dew ADI16 program.

RT-qPCR for TC-83 RNA copy number

COPY NUMBER STANDARD

To prepare the copy number standard (see “TC-83 RT-qPCR control plasmid”), 1µg of the plasmid was digested using SphI (NEB) according to the manufacturer’s protocol. The digested plasmid was cleaned using the ClonTech PCR-cleanup kit as per the manufacturer’s protocol, and transcribed using the MaxiScript T7 kit (Ambion), also using the manufacturer’s protocol. Once transcribed, the plasmid DNA was digested using the DNA-free DNA removal kit (Invitrogen) and the RNA was further purified using the RNAqueous total RNA isolation kit (Ambion), both according to the

manufacturer's protocol. Finally, linearization, transcription, DNase I treatment, and further purification of the copy number standard were visualized for confirmation of each step using a 1% agarose TAE gel. Copy number was calculated using a DS-11 spectrophotometer (DeNovix) to quantify the amount of RNA per microliter. An online calculator (<http://endmemo.com/bio/dnacopynum.php>) used this and the transcript length (1,723bp) to determine the RNA copy number per microliter. Following this, the RNA was diluted to 2×10^{10} copies per μL in $20\mu\text{L}$ aliquots and stored in a cold block at -20°C . RNA was only freeze-thawed once before being discarded.

RT-qPCR

Viral RNA was extracted using the ZR Viral RNA minikit (Zymo) as per the manufacturer's protocol and eluted in $15\mu\text{L}$ nuclease free water. This was stored on ice as the rest of the reaction was prepared.

A standard curve of the above RNA standard was made to total 8, 10-fold dilutions in nuclease-free water ($5\mu\text{L}$ RNA mixed with $45\mu\text{L}$ nuclease-free water). Pipetting was used to mix between each dilution. This was stored on ice while the master mix was prepared.

Real time PCR primers were designed to amplify a portion of the nsP3 gene. The forward (4840F 5'-ATG CCA TGA CTC CAG AAA GAG-3') and reverse (4981R 5'-GGT GAG AAC AAT ATA GGC TGG G-3') primers were diluted to $20\mu\text{M}$ stocks in nuclease-free water, whereas the FAM tagged probe (4926P 5'-/56-FAM/ ACT TCG GCA ATG GAA AGG ATG AGC A/3BHQ_1/-3') was diluted to a $5\mu\text{M}$ stock, also in nuclease-free water. A master mix of reagents was made using $0.5\mu\text{L}$ of the 40X TaqMan RT enzyme, $10\mu\text{L}$ 2X RT-PCR mix, $0.9\mu\text{L}$ 4840F stock primer, $0.9\mu\text{L}$ 2981R stock primer, $1\mu\text{L}$ 4840F stock probe, and $1.7\mu\text{L}$ nuclease-free water per sample (TaqMan RNA-to Ct 1-Step kit, Applied Biosystems). This was vortexed to mix and stored on ice.

To set up the PCR, 10 μ L of viral RNA, standard, or nuclease-free water (as a non-template control) was added to each well in every other column of a 96-well Real Time PCR plate (Applied Biosystems). To this, 30 μ L of the above master mix was added, and a multichannel pipet was used to mix. After thorough mixing, 20 μ L from each well was transferred to the adjacent well and the plate was sealed with optical tape (Applied Biosystems). After the plate was centrifuged at 125 X g for 1 minute, it was loaded into the QuantStudio 6 Flex Real Time PCR System (Applied Biosystems), which was run using a 15 minute RT step at 48°C, followed by a 10 minute hot start at 95°C, and lastly 40 cycles consisting of a 15 second denaturation at 95°C and 1 minute annealing and elongation step at 60°C. Following the run, the copy number calculated using the RNA standard was converted to RNA copy number per mL.

Illumina NGS for TC-83 *in vitro* passaging: Transmission cycle

VIRAL RNA EXTRACTION

Viral RNA was extracted using the Zymo Direct-zol RNA mini kit as per the manufacturer's protocol. 100ng of RNA was used for each ClickSeq library.

CLICKSEQ LIBRARY PREPARATION

ClickSeq was used instead of the traditional Illumina library procedures to avoid the errant recombination that frequently occurs during the typical fragmentation and ligation steps. Instead of RNA fragmentation, SSIII RT-PCR (Invitrogen) is performed using random hexamers attached to an Illumina p7 adapter sequence. In addition to this, azido-NTPs, which cause chain-termination, are added to the NTPs at a 1:35 ratio. In a manner similar to Sanger sequencing, this results in cDNA strands of various sizes. Following this, a modified 5'-hexynyl Illumina sequencing adapter was click-ligated onto the N-terminus of the cDNA strands using a copper-catalyzed azide-alkyne cycloaddition. The cDNA was then purified using a Zymo DNA clean column and

amplified using 18 cycles of OneTaq (NEB) PCR, resulting in the removal of the triazole group linking the cDNA fragment to the 3' Illumina sequencing adapter. Following another Zymo DNA clean column purification, the samples were visualized on an agarose gel. cDNA libraries between 400-700bp were excised and purified using the Zymo Research Gel Recovery kit. Sequencing was performed by the UTMB sequencing core using an Illumina NextSeq 550.

Sequence assembly and analysis

Illumina ClickSeq sequencing analysis was performed by the Fofanov lab at UTMB.

QUALITY AND FILTRATION

The quality for each sample/dataset was assessed using FASTQC (351). The paired-end reads were merged for each sample and then filtered to exclude reads with unknown characters (anything other than A, T, C, G) and low quality (<15 quality score), so that only high quality reads were used during analysis. Additionally, the first 16 bases of each read were trimmed due to nucleotide bias.

REFERENCE SEQUENCE

The analysis was performed using VEEV strain TC-83, complete genome (GenBank accession #: L01443.1) (308).

VIRUS DIVERSITY ANALYSIS

To analyze the variant hotspots, each sample was run through a novel rare variant pipeline (available upon request). The pipeline first maps each read to the reference VEEV genome with perfect match, then unmapped reads are re-mapped with 1 mismatch and added to the final map. The 34 base long reads used in the analyses were validated as viral sequences and not host sequences by analysis of the longest subsequences shared

explicitly (no mismatches allowed) and longest similar (1 mismatch allowed) between viral and host genomes. Positions in which the number of reads mapped with mismatches was higher than perfectly mapped reads or coverage was below 100 were excluded from diversity calculations. Mutation frequency per sample was calculated by summing the per position diversities and normalizing by the number of positions for which diversity was calculated. Shannon Entropy was calculated using the equation $-\sum_i p \log(p)/N$, where p equals the probability of mutation and N equals the number of base calls that can happen at a position (i.e. A, G, C, T, insertion, or deletion).

Those sequences that did not align using Bowtie were processed using ViReMa, a recombination mapper, to determine the incidence of recombination. These reads were normalized to the average number of reads aligning to the virus genome.

Statistics

GraphPad Prism was used to perform all statistical tests, which are described in the text.

RESULTS

Titers during passaging

During passaging in C7/10 and U4.4 mosquito cells, TC-83 3x virus titer was almost always lower than the parent virus (Figure 6.1 A&B), as was also observed during Chapter 3. Virus titers in the serially passaged vertebrate cell lines were stable, with little difference between TC-83 3x and TC-83 (Figure 6.1 C&D). The alternating passages (Figure 6.1 E&F) were a mixture of these two observations, with TC-83 3x titers dropping slightly during the mosquito cell passages (passages 2, 4, and 6) and rebounding during vertebrate cell passages (passages 1, 3, and 5). Except for the U4.4 TC-83 and TC-83 3x passages, no other passage series showed a consistently significant change in titer by PFU or RNA quantity from the first passage as measured by Kruskal-Wallis.

Of interest, the specific infectivity results suggest that TC-83 3x acted more like a low-fidelity mutant in the cell lines without an intact immune response (Figure 6.2 B, D, F), with a higher amount of RNA produced than infectious virus. This seemed to stabilize over the course of passaging, with higher passage numbers of TC-83 3x consistently producing lower specific infectivity values than TC-83. No consistent differences in specific infectivity were observed when TC-83 and TC-83 3x were passaged in the intact immunity cell lines (Figure 6.2 A, C, E).

During passaging, some of the passage series began to produce smaller plaques (Figures 6.3-6.5). When these plaques were measured, one of the TC-83 3x C6/36 passage replicates as well as a TC-83 U4.4 replicate (with the other replicate trending) produced significantly smaller plaques compared to the first passage (Figure 6.5). Because this only occurred in the mosquito cell passages, this suggested that these virus passages were possibly losing fitness in vertebrate cells, as these are what were used for plaque assays.

Genetic Stability

To understand the genetic changes that occurred during passaging, passages 1 and 6 from every passaging condition were prepped using ClickSeq and sequenced using an Illumina NextSeq. Due to low coverage, the first U4.4 passages were not analyzed further.

No SNPs occurred during any of the passage series. For all passage series, changes in mutation frequency (Figure 6.5) and Shannon entropy (Figure 6.6) were small, with no overt pattern of changes in diversity based upon RdRp fidelity or cell type. This was also observed for the number of high frequency variants (Figure 6.7).

The TC-83 3x RdRp mutations were very stable, ranging from a mutation frequency of 0.000048-0.0024 in the final passage (data not shown). Unlike the *in vivo* results in Chapter 4, TC-83 3x produced a small proportion of revertants at the E2

attenuating position, while TC-83 did not produce any. The low amount of TC-83 revertants may have been due to lower coverage at that position, with TC-83 retaining an average coverage of 4639 ± 2200 , while the average TC-83 3x coverage was 7450 ± 2626 . Additionally, although coverage was low at the 3'UTR attenuating mutation (equal to 183 ± 140), neither TC-83 nor TC-83 3x reverted at this position (data not shown).

DISCUSSION

As in other microevolution studies designed to examine the trade-off hypothesis (192-202), the results for these passaging conditions were largely inconclusive, at least after only 6 passages. As changes in fitness were not directly measured (e.g. a competition assay), it is unknown if changes in fitness occurred. However, some of the TC-83 and TC-83 3x mosquito passages began to produce significantly smaller plaques over the course of passaging, which has previously been observed for mosquito cell adapted SINV (398) and EEEV (193). It would be interesting to compete and compare these small plaque passage series against passage series that did not result in significantly smaller plaque sizes to validate the presumed fitness changes.

Similar to other studies that have examined arbovirus microevolution (194, 197, 200), no consensus sequence changes occurred during any of the passage series. However, this does not necessarily mean that no fitness gains occurred, as changes in the minority virus population have been implicated in increased virus fitness (204, 397). Additionally, the changes in virus diversity over the course of passaging were fairly small. In contrast to the specific infectivity results, which suggested stabilization of the low-fidelity phenotype in the immune incompetent cell passages, there was no apparent difference in the virus diversity produced by TC-83 versus TC-83 3x. Perhaps this is due to the ClickSeq library protocol (65), which uses the relatively low-fidelity Taq polymerase (399) to generate its Illumina sequencing libraries. This may ablate the small changes in diversity typically seen for the TC-83 3x mutant. In the future, we need to

directly compare the differences in diversity generated during ClickSeq library preparation versus the standard protocol to ensure that ClickSeq is not obscuring changes in virus fidelity.

Illustration 6.1. In vitro transmission cycle.

To determine differences caused by mosquito and vertebrate cell lines, TC-83 and TC-83 3x were passaged 6 times in duplicate using an MOI of 0.1. Additionally, cell lines with different antiviral immune properties were used to determine how these factors affect the two viruses. U4.4 mosquito cells have an active siRNA response, while C6/36 cells do not. On the other hand, MRC-5 cells can produce and respond to IFN, while Vero cells are not able to produce IFN. During alternating transmission cycles, the passages began using the vertebrate cell lines (i.e. Vero and MRC-5).

Figure 6.1: Virus titer during passaging.

Changes in plaque assay (left y-axis) and RNA copy number (right y-axis) during passaging in U4.4 (A), C6/36 (B), MRC-5 (C), Vero (D), M-U (E), and V-C (F). M-U denotes alternating passage between MRC-5 and U4.4 cells. V-C denotes alternating passage between Vero and C6/36 cells. 3x denotes TC-83 3x. R1 denotes replicate 1, while R2 denotes replicate 2.

Figure 6.2: Specific infectivity during virus passaging.

Changes in specific infectivity (plaque assay:RNA copy number) during passaging in U4.4 (A), C6/36 (B), MRC-5 (C), Vero (D), M-U (E), and V-C (F). M-U denotes alternating passage between MRC-5 and U4.4 cells. V-C denotes alternating passage between Vero and C6/36 cells. 3x denotes TC-83 3x. R1 denotes replicate 1, while R2 denotes replicate 2.

Figure 6.3: TC-83 3x plaque size during passaging.
 Pictures of TC-83 3x replicate 1 plaques for each passage series.

Figure 6.4: TC-83 plaque size during passaging.
 Pictures of TC-83 replicate 1 plaques for each passage series.

Figure 6.5: Plaque size during passaging.

Changes in TC-83 (A, B) and TC-83 3x (C, D) plaque size during passaging in immune competent (A, C) and immune compromised (B, D) cell lines. 3x denotes TC-83 3x. R1 denotes replicate 1, while R2 denotes replicate 2.

Figure 6.6: Mutation frequency during passaging.

Changes in mutation frequency during passaging in C6/36 (A), U4.4 (B), Vero (C), MRC-5 (D), V-C (E), and M-U (F). M-U denotes alternating passage between MRC-5 and U4.4 cells. V-C denotes alternating passage between Vero and C6/36 cells. 3x denotes TC-83 3x. P1 denotes passage 1, while P6 denotes passage 6. U4.4 p1 was not included due to low coverage.

Figure 6.7: Shannon entropy during passaging.

Changes in Shannon entropy during passaging in C6/36 (A), U4.4 (B), Vero (C), MRC-5 (D), V-C (E), and M-U (F). M-U denotes alternating passage between MRC-5 and U4.4 cells. V-C denotes alternating passage between Vero and C6/36 cells. 3x denotes TC-83 3x. P1 denotes passage 1, while P6 denotes passage 6. U4.4 p1 was not included due to low coverage.

Figure 6.8: High frequency variants during passaging.

Changes in the number of high frequency variants (>0.2) during passaging in C6/36 (A), U4.4 (B), Vero (C), MRC-5 (D), V-C (E), and M-U (F). M-U denotes alternating passage between MRC-5 and U4.4 cells. V-C denotes alternating passage between Vero and C6/36 cells. 3x denotes TC-83 3x. P1 denotes passage 1, while P6 denotes passage 6. U4.4 p1 was not included due to low coverage.

Figure 6.9: E2 attenuation reversion.

Reversion of the E2 G8922C mutation that is responsible for TC-83 attenuation.

APPENDIX 2. TC-83 AND RdRp MUTANT VIRUS STOCKS

As different stocks of viruses used for this dissertation demonstrated different phenotypes in chapter 2-4, it was evident that the results for each experiment needed to be considered in terms of the specific virus stock used. Unfortunately, there is no deep sequencing data for most of these stocks, because each vial of stock virus was discarded after use in an experiment and none were saved from these earlier stocks. This appendix contains the known information for each virus stock used in the experiments described in earlier chapters. The methods for this chapter were included in chapters 2-4.

RESULTS AND DISCUSSION

Virus Stocks

While titer varied post-electroporation as measured by plaque assay, there were no significant differences between electroporation titer and the studied phenotypes (Table 7.1). Future stock will incorporate NGS analysis and various phenotypic tests (e.g. attenuation in an infant mouse model) to tease apart differences in virus stock attenuation.

Number	Virus	Hour Post-Electroporation	Stock Titer (PFU/mL)	Infant Mouse Attenuation	Mosquito Cell Attenuation
1	TC-83	36	1.95×10^9	No	No
2	TC-83 3X	36	5.75×10^9	Yes	Yes
3	TC-83 4X	36	3.53×10^6	Yes	n/a
4	TC-83	36	1.43×10^{10}	n/a	No
5	TC-83	36	8.25×10^9	n/a	Yes
6	TC-83	48	2.1×10^8	n/a	n/a
7	TC-83	48	1.15×10^9	n/a	n/a
8	TC-83	72	2.7×10^8	No	n/a
9	TC-83 3X	24	4.15×10^9	No	No
10	TC-83 3X	48	4.2×10^9	n/a	No
11	TC-83 3X	72	1.7×10^8	n/a	n/a
12	TC-83 4X	48	2.85×10^5	n/a	n/a
13	TC-83 4X	72	1.15×10^8	No	n/a
14	TC-83	48	1.95×10^9	No	n/a
15	TC-83 3X	48	1.75×10^9	No	n/a
16	TC-83 4X	48	2.2×10^9	No	n/a

Table 7.1: Virus stocks used in this dissertation.

The virus stocks used in this dissertation are listed above. Infant mouse attenuation refers to attenuation in a SC infant mouse model compared to TC-83. Mosquito cell attenuation refers to the lack of infection when mosquito cells were infected at a low MOI.

Vita

NAME: Tiffany Faye Kautz

PRESENT POSITION AND ADDRESS:

Predoctoral Research Fellow
University of Texas Medical Branch at Galveston
Department of Microbiology and Immunology
4.104 Keiller Building
301 University Blvd.
Galveston, TX 77555-0609
Email: tfkautz@utmb.edu

BIOGRAPHICAL:	Date of Birth:	09/30/1987
	Birthplace:	Manteca, CA
	Father:	Douglas Dean Kautz
	Mother:	Sherilyn Ann Kautz
	Citizenship:	USA

EDUCATION:

08/2012 to present	Predoctoral Research Fellow Department of Microbiology and Immunology The University of Texas Medical Branch, Galveston, TX
05/2011-05/2012	Masters of Science in Biotechnology New Mexico State University, Las Cruces, NM
08/2006-05/2011	Bachelor's of Science in Genetics, Honors New Mexico State University, Las Cruces, NM
08/2006-05/2011	Bachelor's of Arts in Psychology, Honors New Mexico State University, Las Cruces, NM

PROFESSIONAL AND TEACHING EXPERIENCE:

Professional Experience:

08/2013 to present	Predoctoral Research Fellow , Department of Microbiology and Immunology, University of Texas Medical Branch, Galveston, TX Mentor: Naomi Forrester
--------------------	--

Project: Develop and characterize fidelity variants of arboviruses, such as Venezuelan equine encephalitis virus and chikungunya virus.

Project: Examine the ability of low-fidelity versions of live-attenuated vaccines for Venezuelan equine encephalitis virus to increase vaccine safety and enhance immunogenicity.

Project: Examine the stability of low-fidelity mutations in a transmission cycle.

- 08/2013 to present **Predoctoral Research Fellow**, Department of Microbiology and Immunology, University of Texas Medical Branch, Galveston, TX
Mentor: Scott Weaver
Project: Tested human serum and mosquitoes from Mexico, Colombia, and the Dominican Republic for the presence of chikungunya virus and analyzed these for genetic evidence of chikungunya virus adaptation to the secondary chikungunya virus mosquito vector, *Aedes albopictus*.
- 05/2011-05/2012 **Graduate Research Assistant**, Department of Biology, New Mexico State University, Las Cruces, NM
Mentor: Kathryn Hanley
Project: Examined the effects of sylvatic dengue virus infection in the dengue virus reservoir species *Chlorocebus sabaeus* (African green monkey).
- 01/2010-05/2011 **Undergraduate Research Assistant**, Department of Biology, New Mexico State University, Las Cruces, NM
Mentor: Kathryn Hanley
Project: Used siRNA mediated knockdown to study quasispecies diversity in dengue virus.
Project: Examined how dengue virus competition in *Aedes aegypti* mosquitoes affected the ability of sylvatic and endemic dengue virus strains to disseminate.
Project: Determined differences in sialome composition in wild birds in New Mexico to determine relative risk for different types of influenza infection.
- 07/2009-12/2009 **Undergraduate Research Assistant**, Department of Psychology, New Mexico State University, Las Cruces, NM
Mentor: Jim Kroger
Project: Used EEG technology to examine the role of the prefrontal cortex in maintaining attention.
- 09/2008-08/2010 **Undergraduate Research Assistant**, Department of Agriculture, New Mexico State University, Las Cruces, NM
Mentor: Willis Fedio

Project: Improvement of detection methods for *E. coli* O157:H7, *Listeria*, and *Salmonella* in various food products for the FDA.

- 06/2008-08/2008 **Undergraduate Student Researcher**, Bioscience Division, Los Alamos National Laboratories, Los Alamos, NM
Mentor: Norman Doggett
Project: Built a collection of bacteria representing different taxonomic groups for use in PCR assay testing and validation.
- 09/2007-05/2009 **Howard Hughes Scholar**, Department of Psychology, New Mexico State University, Las Cruces, NM
Mentor: Melissa Guynn
Project: Used cognitive psychology techniques to better understand prospective memory.

Teaching Experience:

- 09/2014-12/2014 **Facilitator**, Biochemistry
University of Texas Medical Branch, Galveston, NM

Training and Supervision of Undergraduate, Graduate and Medical Students

- 09/2015-02/2016 Zachary Ahmed, High School Student
- 06/2015-07/2015 Juan David Rodas Gonzalez, Visiting Scientist
- 02/2015-03/2015 Esteban Diaz Gonzalez, Graduate Student
- 02/2015-03/2015 Iliana Malo Garcia, Visiting Scientist
- 11/2015-04/2015 Dawn Auguste, Volunteer
- 11/2014-01/2015 Nicolas Ruiz, Medical School Student
- 11/2014-01/2015 Johnae Snell, Medical School Student
- 11/2014-01/2015 Russell Purpura, Medical School Student
- 11/2014-01/2015 Aidan Deleon, Medical School Student
- 09/2014-05/2015 Rose Coleman, High School Student
- 06/2014-08/2014 Ellie Lewis, Undergraduate Student

GRANT SUPPORT:

- 09/2014-08/2016 McLaughlin Predoctoral Grant
- 09/2016-08/2017 Tropical Diseases T32 Predoctoral Grant

MEMBERSHIPS IN SCIENTIFIC SOCIETIES:

National:

12/2013 to present	Student Member, American Society of Tropical Medicine and Hygiene (ASTMH)
08/2015 to present	Student Member, American Association for the Advancement of Science (AAAS)
02/2016 to present	Student Member, American Society for Virology (ASV)

HONORS AND AWARDS

04/2017	Travel award to IDEAS workshop on Evolutionary Causes and Consequences of Arbovirus Emergence, IDEAS
03/2017	McLaughlin Symposium Poster Award, UTMB
05/2016	Department of Pathology Annual Trainee Research Day Poster Award, UTMB
04/2016	ASV Student Travel Award, ASV
11/2015	Cary and Kay Cooper Scholarship Fund, UTMB
08/2015	AAAS/Science Program for Excellence in Science, UTMB
04/2015	Preventative Medicine and Community Health Poster Award, UTMB
11/2014	Sealy Center for Vaccine Development Travel Award, UTMB
04/2014	McLaughlin Symposium Poster Award, UTMB
12/2013	Am J Trop Med Hyg Student Subscription, UTMB
08/2012	McLaughlin Scholar, UTMB
03/2012	NMSU Arts and Sciences Travel Award, NMSU
08/2006	Tiscowitz Scholarship, NMSU

COMMUNITY SERVICE AND ACTIVITIES:

05/2016 to 10/2017	Student representative for the Microbiology and Immunology curriculum committee. Galveston, TX.
08/2014 to 05/2016	Mentor for BENCH program designed to expose Ball High School students to basic research techniques and the scientific method. Galveston, TX.
05/2014 to present	Member of UTMB biodefense journal club
01/2014	Science fair judge for students at Odyssey Academy. Galveston, TX.
03/2012-05/2012	Facilitator for Minority Biomedical Research Support-Research Initiative for Scientific Enhancement (MBRS-RISE).
09/2007-07/2012	Volunteer, Humane Society, Las Cruces, NM.
